Many techniques have been described for the detection of compounds separated by gas chromatography.

Space limitations, however, allow only those detectors that are widely used and have reached commercial maturity to be discussed in this article. The important spectroscopic detectors (e.g., mass and infrared spectrometry) used for structure elucidation as well as detection are discussed in separate articles.

The principal methods of detection can be categorized as ionization, bulk physical property, optical, and

electrochemical based on the principle of the detection mechanism. Further division into universal, element-selective, and structure-selective detectors is possible based on the characteristics of the detector response. The flame ionization and thermal conductivity detectors (TCDs) respond to nearly all organic compounds and are examples of general or (near) universal detectors. Other detectors respond only to a particular heteroatom (e.g., flame photometric, thermionic ionization, or atomic emission detectors) and are element-selective. Or they respond only to a structural feature related to the bond energy of two or several atoms in a compound (e.g., electron capture and photoionization detectors) and are structure-selective. Element-selective and structure-selective detectors are used for target compound analysis, for example, the analysis of a specific drug in biological fluids or pesticides in an environmental extract, where the matrix is often complex and masks the presence of the target compounds when a universal detector is used.

Detectors can also be compared by figures of merit that define their signal characteristics in quantitative terms. The fundamental properties of general interest are sensitivity, limit of detection, operational response range, response time, and noise characteristics. Sensitivity is defined as the detector response per unit mass or concentration of a substance and is determined as the slope of the calibration curve for detectors with a linear response. A detector with a high sensitivity, corresponding to a larger slope, is better able to discriminate between small differences in sample amounts. Sensitivity is often confused with the limit of detection, the latter defined as the concentration or mass flow of a substance that produces a detector response equal to some multiple (typically three times) of the average detector noise. The dynamic range is defined as the range of sample amount for which a change in sample size induces a discernible change in the detector signal. For many, although not all detectors, the relationship between response and sample amount is linear over a wide range. It is the extent of this range that is generally of most interest for comparing detector performance.

## Ionization Detectors

Common carrier gases behave as near perfect insulators. In the absence of conduction by the gas molecules themselves, the increased conductivity due to the presence of very few charged species is easily measured, providing the low sample detection limits characteristic of ionization-based detectors. Common ionization detectors include the flame ionization detector (FID), thermionic ionization detector (TID), photoionization detector (PID), the electron-capture

detector (ECD), and the helium ionization detector (HID). A different method of ion production is employed by each detector, but in all cases, the quantitative basis of the detector response is due to the change in ion current in the presence of sample vapors.

### Flame Ionization Detector

The popularity of the FID is explained by its near universal response to organic compounds, low detection limits, simple construction, fast response, and exceptional linear range. Only the fixed gases (e.g., He, Xe, H<sub>2</sub>, N<sub>2</sub>), certain nitrogen oxides (e.g., N<sub>2</sub>O, NO, etc.), compounds containing a single carbon atom bonded to oxygen or sulfur (e.g., CO<sub>2</sub>, CS<sub>2</sub>, etc.), inorganic gases (e.g., NH<sub>3</sub>, SO<sub>2</sub>, etc.), water, and formic acid fail to provide a significant response. Typical detection limits correspond to about  $10^{-12}$  g s<sup>-1</sup> with a linear response range of  $10^6$ .

The FID signal results from the combustion of organic compounds in a small hydrogen–air diffusion flame (Figure 1). The column carrier gas is mixed with hydrogen and burned at a narrow orifice in a chamber through which excess air is flowing. The ions produced in the flame are collected by application of a small voltage between the jet tip and a cylindrical electrode located a few millimeters above the flame. The small ion currents ( $10^{-14}$ – $10^{-5}$  A) are amplified by a precision electrometer. Detector performance is influenced primarily by the ratio of air-to-hydrogen-to-carrier (and make-up) gas flow rates, the choice of carrier gas, and detector geometry. The optimum response plateau for detector gas ratios is fairly broad, however, permitting operation over a rather wide range of gas flow rates without incurring a large penalty in diminished response.

On account of the low thermal energy of flames it is believed that ionization results from chemical

**Figure 1** Cross-sectional view of a flame ionization detector.

**Table 1** Contributions of structure to the response of the flame ionization detector

Atom	Type	Effective carbon number
C	Aliphatic	1.0
C	Aromatic	1.0
C	Olefinic	0.95
C	Acetylenic	1.30
C	Carbonyl	0
C	Carboxyl	0
C	Nitrile	0.3

O	Primary alcohol	−0.5
O	Secondary alcohol	−0.75
O	Tertiary alcohol	−0.25
N	In amines	Similar to O in alcohols
Cl	On olefinic C	0.05
Cl	Two or more on aliphatic C	−0.12 per Cl

ionization process, such as the one shown below:

Degradation of organic compounds in the flame likely results from attack by hydrogen atoms causing fission of carbon–carbon bonds. Fission of unsaturated bonds proceeds after hydrogenation. The hydrocarbon radicals produced by fission are unstable and undergo a cascade of fast fractionation and hydrogenation reactions such that all carbon atoms are eventually converted to methane. Consequently, each carbon atom capable of hydrogenation yields the same signal, and the overall FID response to each substance is proportional to the sum of these ‘effective’ carbon atoms. The FID response is highest for hydrocarbons, being proportional to the number of carbon atoms, while substances containing oxygen, nitrogen, sulfur, or halogens yield lower responses, depending on the characteristics of the carbon–heteroatom bond and the electron affinity of the combustion products. The lower response is due to competition between hydrogenation of the carbon–heteroatom bond and hydrogen abstraction with formation of neutral species (e.g., CO, HCN), which are poorly ionized in the flame. The effective carbon number for a particular compound can be estimated by summation of the various carbon and heteroatom contributions (Table 1), which in turn can be used to predict relative response factors with reasonable accuracy.

### Thermionic Ionization Detector

All modern versions of the TID, also known as the nitrogen–phosphorus or NPD detector, employ a ceramic or glass bead or cylinder doped with an alkali metal salt, molded onto an electrical heater wire, heated to 400–800°C, as the thermionic source. Carrier gas is combined with hydrogen at the detector base and flows through a jet where it is mixed

with air. The flow of detector gases is insufficient to establish a flame, but sufficient to maintain a plasma localized around the thermionic source. The thermionic source is located immediately above the jet tip and the cylindrical collector electrode either surrounds the source or is located immediately above it, depending on the detector design. A voltage set between the collector electrode and jet tip allows collection of (usually) negative ions and the ion current is measured by an electrometer.

Two different mechanisms have been proposed to explain the element-selective response of the TID to nitrogen- and phosphorus-containing compounds. These mechanisms differ principally in whether the interaction between the alkali metal atoms and organic fragments occurs as a homogeneous reaction in the gas phase or is purely a surface phenomenon. According to the gas-phase ionization theory, alkali metal atoms are vaporized from the hot source after acceptance of an electron from the heating wire or plasma. While in the boundary layer near the surface of the thermionic source, the alkali metal atoms are excited and ionized by collision with plasma particles. The negatively charged source rapidly recaptures the positively charged metal ions. This cyclic process results in a steady-state population of metal atoms in the boundary layer. If a process that results in ionization of metal atoms disturbs this equilibrium, then more metal atoms will leave the source to restore the equilibrium accompanied by an increase in the ion current. The selectivity of the detector results from the fact that only those radicals with electron affinities equal to or greater than the ionization potential of the metal atoms will contribute to the ion current. Among the many fragments generated by the decomposition of organic compounds in the plasma, only the  $\text{CN}^\bullet$ ,  $\text{PO}^\bullet$ , and  $\text{PO}_2^\bullet$  radicals meet this criterion for the alkali metals.

The surface ionization model assumes that the principal role of the alkali metal in the source is to lower the work function of the surface. Electro-negative decomposition products from phosphorus- or nitrogen-containing compounds are then selectively ionized by extracting an electron from the surface of the thermionic source. These negative ions are responsible for the increase in observed ion current measured at the collector electrode. To account for the influence of experimental variables on the detector response, it is assumed that a combination of the heat from the source and the reaction of sample molecules within the boundary layer are responsible for sample decomposition. The active decomposition products must be similar and largely independent of molecular structure for nitrogen- and phosphorus-containing compounds to account for the narrow range of response factors.

The response of the detector to compounds containing elements other than nitrogen and phosphorus depends on the thermionic source temperature, the work function of the source surface, and the chemical composition of the gas environment surrounding the source. With nitrogen as the plasma gas and a thermionic source with a low work function (high cesium content), the detector can be made selective to compounds containing functional groups of high electron affinity (e.g., nitro and thiol groups). With a relatively low source temperature (400–500°C) and air or oxygen as the plasma gas enhanced selectivity toward halogen-containing compounds is obtained.

Although details of the detector response mechanism are not certain, the TID is not a particularly difficult detector to use and affords reliable results. Typical detection limits for nitrogen-containing compounds are about  $5 \times 10^{-14}$  to  $2 \times 10^{-13}$  g N/s and for phosphorus-containing compounds about  $1 \times 10^{-14}$  to  $2 \times 10^{-13}$  g P/s. The selectivity against carbon is about  $10^3$  to  $10^5$  g C/g N and  $10^4$  to  $5 \times 10^5$  g C/g P. Discrimination against phosphorus in the nitrogen mode is poor at 0.1–0.5 g P/g N. The linear range is about  $10^4$ – $10^5$ . The TID is widely used in environmental and biomedical research for determining pesticides residues and drugs as well as for obtaining element-selective profiles, where its high sensitivity and selectivity are useful in minimizing sample preparation requirements.

### Photoionization Detector

Selective ionization of most organic compounds in the gas phase is possible by absorption of photons with energy either close to or greater than the ionization potential of the compounds. For typical organic compounds this requires photons in the far ultraviolet of about 5–20 eV. A cross-sectional view of a typical PID is shown in **Figure 2**. The photon source is a compact discharge lamp, containing an inert gas or gas mixture at low pressure, which emits monochromatic light of a specific energy, depending on the choice of fill gases and window material. Sources of different nominal energies (8.3, 9.5, 10.2, 10.9, and 11.7 eV) provide

for the possibility of selective ionization of organic compounds with the 10.2 eV source used for general applications (**Table 2**). An optically transparent window made of a metal fluoride separates the discharge compartment from the ionization chamber. The carrier gas passes through the thermostatted ionization chamber and between two electrodes, positioned at opposite ends of the chamber. An electric field is applied between the electrodes to collect the ions formed (or electrons, if preferred) and the current amplified by an electrometer.

An alternative approach is based on an open-source design. Photons are generated by an atmospheric pressure helium discharge that can be doped with other inert gases to provide a range of photon energies. The detector is constructed from a quartz

**Figure 2** Cross-sectional view of a photoionization detector.

**Table 2** Selectivity of the photoionization detector to different compound classes

Photon energy (eV)		Fill gas	Compounds ionized
Nominal	Actual		
8.3	8.44	Xe	Compounds with low ionization potential such as polycyclic aromatic compounds Simple aromatic compounds in the presence of alkanes, mercaptans in H <sub>2</sub> S, amines in ammonia
9.5	8.44 (97.6%)	Xe	
	9.57 (2.1%)		
	10.4 (0.18%)		
10.2	10.03 (82.9%)	Kr	Most organic compounds except permanent gases, C <sub>1</sub> –C <sub>4</sub> alkanes, methanol, acetonitrile, and chloromethanes
	10.64 (17.1%)		
11.7	11.62 (71.8%)	Ar	Low molecular weight compounds with high ionization potentials (e.g., formaldehyde, ethane, chloromethanes, acetylene, etc.)
	11.82 (26.2%)		

tube divided into two zones with electrodes located at the end flanges and middle section. A high-voltage pulse is used to initiate the discharge in the top section and a bias potential on the middle electrode to direct electrons to the collector electrode housed in the bottom section. The carrier gas is introduced at a point close to the middle electrode with photon ionization occurring in the region between the middle electrode and the collector electrode. Since there is no barrier between the source and ionization chamber the pulse discharge PID can be operated at lower wavelengths (13.5–17.8 eV) than the conventional PID design functioning as a near universal detector.

The response of the PID can be described by the relationship

$$i = IF\eta\sigma NL[AB]$$

where  $i$  is the detector ion current,  $I$  the initial photon flux,  $F$  the Faraday constant,  $\eta$  the photoionization efficiency,  $\sigma$  the absorption cross-section,  $N$  Avogadro's number,  $L$  the path length, and  $[AB]$  the concentration of an ionizable substance. Thus, for a particular detector and source, the PID signal is proportional to the ionization yield, absorption cross-section, and molar concentration of the analyte. The product ( $\eta\sigma$ ) is the photoionization cross-section, which expresses both the probability that a molecule will absorb a photon and the probability that the excited state will ionize. A number of secondary processes involving collisions with carrier gas molecules and electron-capturing impurities compete with the ionization mechanism reducing the detector signal. Detector design and control of the operating conditions minimize these effects.

The PID is inexpensive, of rugged construction, and easy to operate. Due to the low efficiency of photoionization (<0.1%) the detector is classified as nondestructive. Since no combustion gases are required the PID can be used in environments where combustion gases are considered hazardous or in portable instruments, where the additional weight of several gas bottles is undesirable. For compounds with favorable ionization properties the PID is 5–50 times more sensitive than the FID with a comparable linear range ( $\approx 10^7$ ). For individual compounds detector response factors vary over a wide range allowing the PID to be used as a selective detector for some applications. Major uses include the analysis of volatile organic compounds from environmental samples and in field-portable gas chromatographs.

### Electron-Capture Detector

The ECD owes its popularity to its unsurpassed sensitivity to a wide range of environmentally important and biologically active compounds. Examples of

general applications include the determination of pesticides and industrial chemicals in the environment, assessment of the fate of ozone-depleting chemicals in the upper atmosphere, and the determination of drugs and hormones in biological fluids. To maintain optimum detector performance some experience with the operation of the detector is required as well as familiarity with the causes and effect of detector contamination.

The ECD is available in several different designs dominated by two alternative methods for generating thermal electrons responsible for the detector's operating characteristics. From inception, high-energy  $\beta$  electrons generated by the decay of a radioisotope have been used as the primary source of ionizing radiation. Either  $^{63}\text{Ni}$  or  $^3\text{H}$  radioisotope sources supported by a metal foil are used in commercial detectors. These  $\beta$ -particle emitters produce a large number of secondary electrons through multiple collisions with carrier gas molecules forming a plasma of thermal electrons (mean energies 0.02–0.05 eV), radicals, and positive ions. Radioisotope-based detectors require periodic wipe tests to ensure safety as well as compliance with regulations concerning storage, use, and transport of radioactive materials. Regulatory constraints provided the impetus for the development of a non-radioactive detector. The non-radioactive ECD uses high-energy photons from a pulsed discharge in pure helium to ionize a support gas added downstream of the discharge. A plasma of thermal electrons and positive ions is formed in the ionization chamber with properties similar to the plasma generated by the radioisotope-source ECD.

Application of a fixed or pulsed potential to the ionization chamber allows collection of the thermal electrons establishing the standing (or baseline) current. When an electron-capturing compound enters the ionization chamber, thermal electrons are removed by formation of negative ions. The increased rate of neutralization of these ions by positive ions, or their reduced drift velocity during collection of the thermal electrons, is responsible for the detector signal. In contrast to the other ionization detectors a decrease in the detector standing current proportional to solute concentration is measured rather than an increase in the number of ions or electrons produced.

The majority of detectors with radioisotope sources in current use are based on either the coaxial cylinder or asymmetric configurations, as shown in **Figure 3**. The low specific activity of the  $^{63}\text{Ni}$  source requires a relatively larger source area to provide a suitable background current that is easier to accommodate in these designs. Virtually all contemporary detectors employ pulse-sampling techniques to collect the thermal electrons based on the variable frequency constant

current mode. In this case, the pulse frequency is varied throughout the separation to maintain the cell current at a fixed reference value. The detector signal is a voltage proportional to the pulse frequency. The two principal advantages of this method are an increased linear response range of  $10^4$ – $10^5$  and reduced detector disturbance from column contamination except for a few compounds with ultrafast electron attachment rate constants, which exhibit a nonlinear response, and are better measured with a constant pulse frequency.

Oxygen-free nitrogen is the most common carrier gas for packed columns and hydrogen or helium for open tubular columns. Argon–methane or nitrogen is then added as make-up gas at the column exit to minimize extra column peak broadening due to the relatively large effective detector volume. Pure argon and helium are unsuitable make-up gases as they readily form metastable species, which can transfer

their excitation energy by collision with sample vapors, resulting in undesirable ionization effects (Penning reaction). The addition of 5–10% of methane to argon removes these ions by deactivating collisions as quickly as they are formed. Oxygen and water vapor traps should be used to purify all gases.

The ECD is a structure-selective detector with a response range that covers about seven orders of magnitude (Table 3). The greatest response is observed for compounds containing halogen atoms ( $I > Br > Cl \gg F$  increasing synergistically for multiple substitution on the same carbon atom) or nitro groups, to organometallic compounds, and to compounds containing conjugated electrophores. This latter group is the least well defined, and is comprised of compounds containing two or more weakly electron-capturing groups, connected by some specific bridge that promotes a synergistic interaction between the two electron-capturing groups. Examples of compounds containing conjugated electrophores include conjugated carbonyl compounds (benzophenones, quinones, phthalate esters, coumarins), some polycyclic aromatic hydrocarbons, some sulfonamides, and certain steroids.

The effect of temperature on the detector response is frequently overlooked. The detector response can vary by as much as 100–1000-fold for a  $100^\circ\text{C}$  change in detector temperature. In most cases electron capture occurs by either of two mechanisms. By non-dissociative electron capture resulting in the formation of a stable molecular ion, or by dissociative electron capture with formation of a molecular ion in an excited state that instantaneously decomposes with elimination of a negative ion fragment. Nondissociative electron capture is generally associated with compounds containing a conjugated electrophore and dissociative electron capture with halogen-containing compounds. An increase in detector temperature favors the populating of vibrationally excited states

**Figure 3** Cross-sectional view of a coaxial cylinder (A) and asymmetric (B) electron-capture detector.

**Table 3** Relative response of the electron-capture detector to various organic compounds

General organic compounds	Relative response	Fluorocarbon compounds	Relative response
Benzene	0.06	$\text{CF}_3\text{CF}_2\text{CF}_3$	1.0
Acetone	0.50	$\text{CF}_3\text{Cl}$	3.3
Di- <i>n</i> -butyl ether	0.60	$\text{CF}_2=\text{CFCl}$	$1.0 \times 10^2$
Methylbutyrate	0.90	$\text{CF}_3\text{CF}_2\text{Cl}$	$1.7 \times 10^2$
1-Butanol	1.00	$\text{CF}_2=\text{CCl}_2$	$6.7 \times 10^2$
1-Chlorobutane	1.00	$\text{CF}_2\text{Cl}_2$	$3.0 \times 10^4$
1,4-Dichlorobutane	15.00	$\text{CHCl}_3$	$3.3 \times 10^4$
Chlorobenzene	75.00	$\text{CHCl}=\text{CCl}_2$	$6.7 \times 10^4$
1,1-Dichlorobutane	$1.1 \times 10^2$	$\text{CF}_3\text{Br}$	$8.7 \times 10^4$
1-Bromobutane	$2.8 \times 10^2$	$\text{CF}_2\text{ClCFCl}_2$	$1.6 \times 10^5$
Bromobenzene	$4.5 \times 10^2$	$\text{CF}_3\text{CHClBr}$	$4.0 \times 10^5$
Chloroform	$6.0 \times 10^4$	$\text{CF}_3\text{CF}_2\text{CF}_2\text{I}$	$6.0 \times 10^5$
1-Iodobutane	$9.0 \times 10^4$	$\text{CF}_2\text{BrCF}_2\text{Br}$	$7.7 \times 10^5$
Carbon tetrachloride	$4.0 \times 10^5$	$\text{CFCl}_3$	$1.2 \times 10^6$

and thus the dissociative mechanism. Conversely, nondissociative electron capture may be destroyed if the rate constant for thermal detachment is too fast, and a higher detector response is usually observed at low detector temperatures. The optimum detector response for practical work is usually obtained at either the maximum temperature recommended for the radioisotope source for compounds with a dissociative mechanism for electron capture, or at the lowest practical operating temperature for compounds with a nondissociative mechanism of electron capture.

### Helium Ionization Detector

The HID is a universal and ultrasensitive detector used primarily for the analysis of permanent gases and some volatile organic compounds that have a poor response to the FID and are present in too low a concentration for detection with a TCD. Typical detection limits are around  $10^{-13} \text{ g s}^{-1}$  with a linear range of about  $10^4$ . Many features of the design of the HID are similar to those of the pulsed discharge ECD. Metastable helium ions thought to be primarily responsible for ionization of organic compounds are produced by bombardment of helium atoms with high-energy  $\beta$ -particles from a radioisotope source (e.g.,  $^{63}\text{Ni}$ ) or produced directly in a pulsed discharge. The HID has a reputation as a difficult detector to use and must be operated under stringent conditions with respect to contamination from carrier gas impurities and the ingress of air or column bleed. Because applications have remained focused on inorganic gases and simple volatile organic compounds, gas-solid columns are often used for separations to minimize contamination problems and drifting baselines with contaminated liquid stationary phases.

### Bulk Physical Property Detectors

Bulk physical property detectors respond to some difference in a carrier gas property due to the presence of the sample. Usually, a large signal for the carrier gas property is desirable to provide a reasonable working range, but for low sample concentrations the detector signal corresponds to a very small change in a large signal, and is noise limited. The sensitivity of the bulk physical property detectors tends to be poor compared with ionization detectors. The most important of the bulk physical property detectors is the TCD. Other examples include the gas density balance and ultrasonic detector.

### Thermal Conductivity Detector

The TCD is a universal, nondestructive, concentration-sensitive detector that responds to the difference in thermal conductivity of the carrier gas and the

carrier gas containing sample. It is generally used to detect permanent gases, light hydrocarbons, and compounds that respond poorly to the FID. Typical detection limits are  $10^{-6}$  to  $10^{-8} \text{ g}$  per peak with a linear range of about  $10^4$ . If lower detection limits are required for compounds with a poor response to the FID, then the HID is a suitable alternative.

In a typical TCD, the carrier gas flows through a heated thermostatted cavity that contains the sensing element, either a heated metal wire or thermistor. With carrier gas flowing through the cavity the heat loss from the sensor is a function of the temperature difference between the sensor and cavity and the thermal conductivity of the carrier gas. When carrier gas containing sample vapors enters the cavity, there is a change in the thermal conductivity of the carrier gas mixture resulting in a change in the sensor temperature. The sensor may be operated in a constant current, constant voltage, or constant mean temperature mode as part of a Wheatstone bridge circuit. A temperature change in the sensor results in an out-of-balance signal proportional to the concentration of sample vapor in the sensor cavity.

The TCD has appeared in several different designs, some of which have advantages for particular applications. They usually represent some variation of the three basic geometries: the flow-through, semidiffusion, and diffusion cells. In the flow-through cell, carrier gas passes over the sensor and in the diffusion cell the sensor is located in a recess into which a portion of the carrier gas stream enters by diffusion. The diffusion and semidiffusion cells have a slow response and are relatively insensitive. They are used mainly for packed column analytical and preparative gas chromatography. Flow-through cells with volumes of 1–100  $\mu\text{l}$  are easily fabricated for use with open tubular columns. To improve thermal stability two or four cells are mounted in the detector oven block, half of which are used as reference cells through which only carrier gas flows, generating a difference signal proportional to sample concentration. In an alternative design, flow modulation is used to switch the carrier gas between two channels, one of which contains a single filament (**Figure 4**). Every 100 ms a switching valve fills the filament channel alternately with carrier gas and column effluent. With an effective detector volume of 3.5  $\mu\text{l}$ , it can be used with even narrow bore open tubular columns.

Carrier gases of low molecular weight and high thermal conductivity (e.g.,  $\text{H}_2$  and  $\text{He}$ ) are required to maximize the detector response and to maintain a large linear response range. Heavier carrier gases such as nitrogen, as well as influencing sensitivity and linearity, may give rise to negative or split top sample peaks. A number of response factor compilations for

**Figure 4** Schematic diagram of a single-filament thermal conductivity detector with flow modulation. In (A) the carrier gas is directed to flow over the filament and in (B) bypasses the filament.

different carrier gases are available, usually expressed on a weight or molar response basis relative to benzene. These values are generally sufficiently accurate for estimating sample concentrations. For more accurate results it is necessary to calibrate the detector for each substance individually.

## Optical Detectors

The use of flames as atom reservoirs is a well-established technique in atomic spectroscopy. The principal emission lines for most nonmetallic elements of interest for gas chromatography occur in the ultraviolet region, where flame background contributions are troublesome. About 28 elements, including phosphorus and sulfur, can be determined by their chemiluminescence emission in hydrogen-diffusion flames with a flame photometric detector (FPD). For direct atomic emission detection, microwave induced and inductively coupled plasmas provide more appropriate atom sources for organic compounds. A number of chemiluminescence reaction detectors are also used in gas chromatography for the specific detection of sulfur- and nitrogen-containing compounds and nitrosamines.

### Flame Photometric Detector

The FPD is an element-selective detector commonly used for the determination of sulfur- and phosphorus-containing compounds. The FPD uses a hydrogen-diffusion flame to first decompose and then excite to a higher electronic state the fragments generated by the combustion of sulfur- and phosphorus-containing

**Figure 5** Cross-sectional view of a flame photometric detector. (Reproduced with permission from Patterson PL, Howe RL, and Abushumays A (1978) Dual-flame photometric detector for sulfur and phosphorus compounds in gas chromatographic effluents. *Analytical Chemistry* 50: 339–344.)

compounds in the effluent from a gas chromatograph. These excited state species subsequently return to the ground state, emitting characteristic band spectra. This emission is isolated by a filter and monitored by a photomultiplier detector.

In the single-flame detector the carrier gas and air are mixed, conveyed to the flame tip, and combusted in an atmosphere of hydrogen. With this burner and flow configuration interfering emissions from hydrocarbons occur mainly in the oxygen-rich flame regions close to the burner orifice, whereas sulfur and phosphorus emissions occur in the diffuse hydrogen-rich upper portions of the flame. Problems with solvent flameout, hydrocarbon quenching, and structure–response variations for different sulfur- and phosphorus-containing compounds with the single-flame detector can be partially overcome using a dual-flame design (Figure 5). The lower flame is hydrogen rich and functions as a matrix-normalization reactor in which all compounds are decomposed to a highly reduced state (e.g.,  $\text{H}_2\text{S}$ ,  $\text{S}_2$ ,  $\text{H}_2\text{O}$ ,  $\text{CH}_4$ , etc.). The combustion products from the first flame are swept into a second longitudinally separated flame where the desired optical emission is generated under optimized flame conditions. The pulsed-flame detector is based on a flame source and flame gas flow rates that cannot sustain a continuous flame. The combustion gases ( $\text{H}_2$  and air) are mixed together in a small chamber and flow to a continuously heated wire igniter. The ignited flame then propagates back to the gas source and is self-terminated once all of the combustible gas mixture present in the combustion path is consumed. The continuous gas flow removes the combustion products and creates additional ignition in a periodic fashion. The pulsed flame emission provides enhanced detection sensitivity and selectivity by time resolution of the various

flame luminescent species. The luminescence from hydrocarbon and flame combustion products (e.g.,  $\text{OH}^*$ ,  $\text{CH}^*$ ,  $\text{C}_2^*$ , etc.) is limited to the time duration for the flame front to pass across the photomultiplier viewing area. Because of lower bond energies the sulfur- and phosphorus-containing species continue to emit in the cooler, yet reactive, postpulse flame conditions. By gating the detector the heteroatom emission can be time resolved from the hydrocarbon and flame background emission.

In the relatively low-temperature and hydrogen-rich flame, sulfur-containing compounds are decomposed to species such as  $\text{H}_2\text{S}$ ,  $\text{HS}$ ,  $\text{S}$ ,  $\text{S}_2$ ,  $\text{SO}$ , and  $\text{SO}_2$  in relative proportions that depend on the flame chemistry. Excited state  $\text{S}_2^*$  species are formed from these primary species in low yield by several two- or three-body collision reactions. The relaxation of  $\text{S}_2^*$  results in broadband emission over the wavelength range from 320 to 460 nm with a maximum emission at 394 nm. The response for sulfur is inherently nonlinear and proportional to the concentration of sulfur atoms entering the flame ( $[\text{S}]^n$ ). The theoretical value for  $n$  is 2, but in practice, values between 1.6 and 2.2 are frequently observed for the single-flame detector. Nonoptimized flame conditions, compound-dependent decomposition, hydrocarbon quenching, and competing flame reactions that lead to de-excitation all contribute to the deviation of  $n$  from its theoretical value. Decoupling the compound decomposition process from the excitation process in the dual-flame and pulsed-flame detectors results in a more truly quadratic response.

In the case of phosphorus, phosphorus-containing compounds are first decomposed to  $\text{PO}$  molecules and finally to electronically excited  $\text{HPO}^*$  species in three-body collisions. A linear relationship between detector response and the concentration of phosphorus atoms entering the flame is expected for phosphorus-containing compounds, at least for low sample concentrations.

Typical detection limits are  $5 \times 10^{-13}$  to  $1 \times 10^{-14}$  g P/s (all detector types) and  $5\text{--}50 \times 10^{-12}$  g S/s (single flame),  $1 \times 10^{-11}$  g S/s (dual flame), and  $2 \times 10^{-13}$  g S/s (pulsed flame). The linear range for phosphorus usually exceeds  $10^3$  while the selectivity is more than  $5 \times 10^5$  g C/g P. Sulfur selectivity varies in the range  $10^4\text{--}10^6$  g C/g S (single flame),  $10^3\text{--}10^4$  g C/g S (dual flame), and  $>10^7$  g C/g S (pulsed flame).

### Chemiluminescence Detectors

Nitrosamines can be detected after thermal cleavage and nitrogen-containing compounds after oxidation to nitric oxide, which reacts with ozone to form nitrogen dioxide in an excited state with photon emission in the near-infrared around 1200 nm.

Sulfur-containing compounds can be decomposed by thermal oxidation to sulfur monoxide and subsequently reacted with ozone to form sulfur dioxide in an excited state with photon emission centered  $\sim 360$  nm.

A typical chemiluminescence detector consists of a series-coupled thermal decomposition and ozone reaction chambers. The selective detection of nitrosamines is based on their facile low-temperature ( $275\text{--}300^\circ\text{C}$ ) catalytic pyrolysis to release nitric oxide. Thermal decomposition in the presence of oxygen at about  $1000^\circ\text{C}$  affords a mechanism for conversion of nitrogen-containing compounds to nitric oxide (catalytic oxidation at lower temperatures is also possible). Decomposition in a hydrogen-diffusion flame or thermal oxidation in a ceramic furnace is used to produce sulfur monoxide from sulfur-containing compounds.

The products of the conversion reaction flow into the ozone reaction chamber, which is maintained at a pressure of 10–30 mmHg. Reduced pressure operation has three advantages: it improves sensitivity by diminishing collisional deactivation of the excited state reaction products; it prevents condensation of water in the reaction chamber; and it reduces the effective detector volume maintaining compatibility with open tubular columns. Ozone is generated by a high-voltage discharge in air or oxygen and enters the reaction chamber by a separate connection. The chemiluminescence emission produced is isolated by an optical filter and detected by a photomultiplier. If one of the reactants in the chamber is maintained in large excess (e.g., ozone), the reaction becomes pseudofirst order for the other reactant, resulting in a linear response.

The most important applications of the chemiluminescence detector are the determination of volatile nitrosamines in food, environmental, and industrial products (detection limits  $\sim 0.5$  ng per peak with a linear range of  $10^3$ ) and sulfur-containing compounds in complex matrices, for example, in the petroleum and gas industries for process control and regulatory compliance, and in the beverage industry to characterize flavor compounds. The response of the chemiluminescence detector to sulfur-containing compounds is almost equal on a per gram of sulfur basis. This allows the use of a single calibration curve for the determination of all sulfur-containing compounds in many cases. The detection limit for the flame-based detector is about  $10^{-12}$  g S/s, with a linear range of  $10^4\text{--}10^5$ , and selectivity  $>10^6$  g C/g S. For the flameless detector the detection limit is about  $10^{-13}$  g S/s, with a linear range of  $10^4\text{--}10^5$ , and selectivity  $>10^7$  g C/g S. In the nitrogen-selective mode detection limits are about  $10^{-12}$  g N/s, with a linear range of  $10^4\text{--}10^5$ , and selectivity  $10^7$  g C/g N.

### Atomic Emission Detector

The atomic emission detector (AED) is a relatively complex instrument and is described below in outline only. Coupling of the separation column to the thermostatted microwave cavity is made through a heated transfer line. The plasma is produced in a thin-walled silica discharge tube within a microwave 'reentrant' cavity (Figure 6). Power is supplied by a magnetron, and coupled to the plasma through a waveguide. The exit of the cavity is closed with a fused silica window and purged with helium to prevent back-diffusion of air into the cavity, and to allow flow reversal so that the solvent peak can be vented in front of the cavity to minimize carbon build-up in the cavity. The plasma is generated in an atmospheric pressure flow of helium made up of the column flow and additional make-up flow, as required. Depending on the elements being determined, low concentrations of various scavenger gases (e.g., O<sub>2</sub>, H<sub>2</sub>, and CH<sub>4</sub>) are also

**Figure 6** Cross-sectional view of the cavity block of an atomic emission detector. (Reproduced with permission from Sullivan JJ and Quimby BD (1989) Detection of C, H, N and O in capillary gas chromatography by atomic emission. *Journal of High Resolution Chromatography* 12: 282–286.)

added. An elliptical mirror collects emissions from 2 mm inside the end of the discharge tube. The emission sensor consists of a flat focal-plane spectrometer with a movable photodiode array detector with a range of about 25 nm. This determines which element combinations can be measured simultaneously. In general, up to four elements can be detected and displayed as element-specific chromatograms at the same time. Typical figures of merit are summarized in Table 4. Obviously, the AED is capable of replacing most of the element-selective detectors described in this article. It is more complex and expensive to operate, however, and has made only modest inroads into the detector market place. On the other hand, it is almost uniquely suited to the detection of organometallic compounds.

In theory, it should be possible to determine the empirical formula for each compound in the chromatogram from the ratio of the AED response to the individual elements. A lack of plasma stability, incomplete compound destruction, and deviations from linearity of the individual element responses, however, limits the accuracy of such measurements. Accurate formula values for oxygen and nitrogen can be particularly difficult to determine due to entrainment of atmospheric gases into the plasma. In addition, it is not always possible to use a single compound internal standard for quantification with the desired accuracy for the same reasons that affect the accuracy of empirical formula determinations.

### Electrochemical Detectors

There are two general problems associated with electrochemical detection in the gas phase. First, few electrochemical detectors are gas-phase sensing devices, and therefore the separated sample components must be transferred into solution for detection.

**Table 4** Response characteristics of the atomic emission detector to different elements

Element (X)	Wavelength (nm)	Minimum detectable amount (pg s <sup>-1</sup> )	Selectivity (g C/g X)	Linear range
C	193.1	2.6		2 × 10 <sup>4</sup>
H	486.1	2.2		6 × 10 <sup>3</sup>
Cl	479.5	39	2.5 × 10 <sup>4</sup>	2 × 10 <sup>4</sup>
Br	470.5	10	1.1 × 10 <sup>4</sup>	1 × 10 <sup>3</sup>
F	685.6	40	3.0 × 10 <sup>4</sup>	2 × 10 <sup>3</sup>
S	180.7	1	3.5 × 10 <sup>4</sup>	1 × 10 <sup>4</sup>
P	177.5	1	5.0 × 10 <sup>3</sup>	1 × 10 <sup>3</sup>
N	174.2	15	2.0 × 10 <sup>3</sup>	4 × 10 <sup>3</sup>
N	388	15	8.0 × 10 <sup>5</sup>	1 × 10 <sup>4</sup>
O	777.2	50	3.0 × 10 <sup>4</sup>	3 × 10 <sup>3</sup>
Sn	303.1	0.5	3.0 × 10 <sup>4</sup>	1 × 10 <sup>3</sup>
Se	196.1	4	5.0 × 10 <sup>4</sup>	1 × 10 <sup>3</sup>
Hg	253.7	0.1	3.0 × 10 <sup>6</sup>	1 × 10 <sup>3</sup>

Second, the majority of organic compounds separated by gas chromatography are neither electrochemically active nor highly conducting. The electrolytic conductivity detector (ELCD) solves both of these problems by decomposing the gas-phase sample into small inorganic molecules, which are detected by their conductivity in a support solvent. The ELCD is used primarily as an element-selective detector for halogen-, sulfur-, and nitrogen-containing compounds.

The carrier gas is mixed with a reaction gas and then passed through a small diameter nickel tube at 850–1000°C. The nickel tube acts as catalyst for the decomposition reaction. With hydrogen as the reaction gas, halogen-containing compounds are converted to hydrogen halide (HCl, HBr), and nitrogen-containing compounds are converted to ammonia. Sulfur-containing compounds are reacted with air to produce sulfur dioxide with a small amount of sulfur trioxide. A chemical scrubber mounted at the exit of the reaction tube is used as needed to enhance the specificity of the detection process. For example, silver wires are used to remove hydrogen halides or hydrogen sulfide, potassium hydroxide supported on quartz fibers to remove acidic species, and aluminum silicate to remove sulfur oxides.

The reaction products from the furnace are swept into a gas–liquid contactor where they are mixed with an appropriate solvent (Figure 7). The support solvent is selected to promote ionization of the reaction species over ionization of interfering compounds. This solvent is usually circulated through a closed system containing beds of ion exchange resins to purify and condition the solvent for reuse. From the gas–liquid contactor the support solvent flows to the conductivity cell, where detection takes place, either after separation of the liquid from insoluble

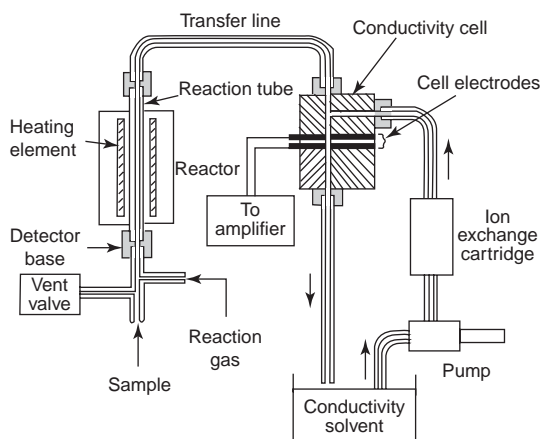

gases, or as a mixed phase, depending on the detector design.

The ELCD has the reputation of being a demanding detector to operate and its popularity has declined as other element-selective detectors with simpler operating features became available. Common practical problems include the loss of response, excessive noise, poor linearity, and poor peak shape. The ELCD is capable of high sensitivity and selectivity with detection limits of about  $10^{-12}$  g N/s,  $10^{-12}$  g S/s, and  $5 \times 10^{-13}$  g Cl/s with a linear range of  $10^3$ – $10^5$ . Selectivity varies with the heteroatom detected as well as detector operating conditions. Values of  $10^4$ – $10^9$  g C/g N, S, or Cl are possible. The ELCD is used primarily for the determination of chlorine- and nitrogen-containing compounds in environmental samples and for the determination of sulfur-containing compounds in petroleum products.

## Mass Spectrometry

D J Harvey, University of Oxford, Oxford, UK

### Introduction

The coupling of gas chromatography (GC) with mass spectrometry (MS), techniques that both employ the sample in the gas phase, was first achieved in 1957. Since then, GC-MS has developed into one of the most sensitive and selective analytical methods for the separation, identification, and quantification of components of complex organic mixtures. It gives a two-dimensional identification consisting of both a GC retention time and a mass spectrum for each component of the mixture. This dual approach is particularly useful for isomer differentiation where good GC separation frequently compensates for difficulties encountered as a result of indeterminate mass spectra. Conversely, the mass spectrum allows structural features to be assigned to the compound producing the GC peak and often provides unambiguous structural assignment. Although the method is limited to the analysis of those compounds that can be made volatile, without thermal decomposition, many compounds that initially fail this requirement can be successfully handled after chemical derivatization.

The early success in the development of this so-called hyphenated technique owes much to the general compatibility between the two methods in terms of sample size and volatility. The only major difference is that the exit from the gas chromatographic column is at low ( $10^{-6}$  Torr), rather than at atmospheric pressure. Nevertheless, modern systems provide excellent GC and MS performance without significant compromise to the behavior of either technique.

### Instrumentation

The instrumentation consists essentially of three components: the gas chromatograph, the mass spectrometer, and a data system (Figure 1). The latter component can be used both for data acquisition and processing, and for instrument control. In systems where packed GC columns are used, an interface is included between the column and the spectrometer to reduce the carrier gas flow from  $\sim 30 \text{ ml min}^{-1}$  to  $\sim 1.5\text{--}2 \text{ ml min}^{-1}$  so that it can be handled by the mass spectrometer's vacuum system. However,

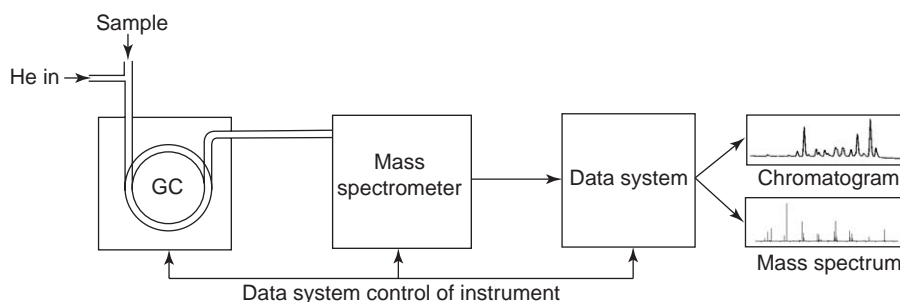

modern systems usually employ capillary columns made up of polyimide-coated fused silica that are interfaced directly with the mass spectrometer. In addition to the above equipment, GC-MS instruments may also be provided with additional features such as an autosampler, an infrared spectrometer, or a flame-ionization detector.

### The Gas Chromatograph

Almost any commercial gas chromatograph can be interfaced to a mass spectrometer and, although its operation is similar to that when used in the stand-alone mode, there are certain features that are specific to successful GC-MS operation.

Column dimensions and carrier gas flows for packed columns tend to be similar to those normally used for stand-alone GC. However, with capillary columns that are interfaced without a separator, the carrier gas flow needs to be fairly low and, consequently, narrow-bore columns with internal diameters of 0.35 mm or less are generally used. Typical columns are 5–30 m long with internal diameters of 0.25 or 0.32 mm. Although columns with internal diameters of 0.53 mm can be used, these usually require a splitter to reduce the flow into the mass spectrometer. Care must be taken with the metal-coated columns, used for high-temperature work, as the metal can short out the ion source voltage. This problem can be avoided by removing the metal coating from the terminal 2–3 cm of the column.

Both gas/solid adsorption and gas/liquid partition chromatography can be used for GC-MS, but GC is by far the most common. Because, in GC, the stationary phase is a liquid, usually a polymer, its vapor pressure will cause a continual low flow, or bleed into the ion source of the mass spectrometer. This bleed, which usually consists of decomposed stationary phase, will produce a spectrum whose intensity increases with column temperature. Stationary phases should therefore be of the high-boiling, low-bleed type. Most currently used stationary phases for routine GC-MS are based on alkyl-polysiloxanes or alkyl-phenyl-polysiloxanes that are chemically bonded to the column wall to increase stability. Columns containing such phases can, in some cases, be used at temperatures of up to 400°C. One advantage, however, to the presence of bleed peaks in the spectrum is that they enable a continual check to be made on the mass spectrometer calibration. For the alkyl siloxanes, ion peaks are present, in decreasing relative abundance, at  $m/z$  73, 207, 281, 355, 429,

**Figure 1** Block diagram of a typical GC–MS system.

503, and 577. The 74 mass unit intervals correspond to O–Si(Me)<sub>2</sub>.

### The GC–MS Interface

Much of the earlier literature on GC–MS instrumentation was concerned with the construction and operation of devices for removing much of the carrier gas from packed column effluents while, at the same time, achieving maximum sample transfer to the mass spectrometer. However, as the use of fused silica capillary columns is now nearly universal, separators for interfacing packed columns retain little more than historical interest.

**Interfacing packed columns** Removal of the excess of carrier gas is most frequently achieved by utilizing the relative diffusion differences between the carrier and the sample molecules. The most widely used device is the jet molecular separator in which the column effluent is allowed to pass through a small jet into an evacuated chamber where it expands. A skimmer placed ~1–2 mm away from the inlet jet captures the center of the effluent stream containing much of the analyte, while allowing most of the carrier gas, which has undergone more rapid lateral diffusion because of its lower molecular weight, to be removed by the pumping system. Helium is invariably used as the carrier gas to maximize the effect, and enrichment factors of greater than 20 are frequently achieved. A similar device is the frit-type or Watson–Biemann separator. This works in an analogous manner in that the carrier gas is removed by lateral diffusion through a fritted glass or ceramic tube through which the column effluent passes. In a third method, the column effluent passes over a silicone rubber membrane through which the organic molecules diffuse into the mass spectrometer. This system, however, has never been widely used, as it tends to cause a reduction in GC resolution.

**Interfacing capillary columns** Direct introduction of the capillary column into the ion source of the

mass spectrometer is now the most generally used method for interfacing the two techniques. However, the presence of the mass spectrometer vacuum results in a much greater pressure drop across the column than would be encountered in normal gas chromatographic operation, and this has led to concern, usually unjustified, about the maintenance of GC resolution. To overcome this difficulty, an open-split interface can be employed. Here, a small gap separates the column from the transfer line that leads the effluent into the ion source. This gap is bathed with helium and, by suitable adjustment of the helium pressure, the exit of the column can be maintained at atmospheric pressure with good sample transfer into the mass spectrometer.

### The Mass Spectrometer

Most types of mass spectrometer can be adapted to take the effluent from a GC column, provided the ion source pumping is sufficient to remove the carrier gas. Quadrupole instruments, in which ion separation is achieved by allowing the ions to drift between four concentric rods carrying DC and AC potentials, are probably best adapted to the technique because of their fast scanning properties and the absence of high ion source potentials. The ion trap, which can be regarded as a development of the quadrupole ion filter, provides a cheap but, at present, limited mass range detector, but can give varying spectra depending on the residence time of the ions in the trap. Ions that remain for longer periods tend to undergo reactions by collision with gas molecules, with the result that electron impact (EI) spectra can acquire some chemical ionization (CI) character (see below). Magnetic sector instruments, in which ion separation is achieved by passage through a magnetic field, allow high-resolution spectra to be acquired for the calculation of elemental compositions. Although maximum scan speeds are lower than with quadrupole-based systems, as a result of magnetic hysteresis, they are sufficient for most applications. More recently, time-of-flight (TOF) instruments have been

adapted for monitoring GC column effluents. In order to accommodate the requirement for a pulsed source of ions, a voltage applied to a 'pusher plate' pulses successive bursts of ions orthogonally into the analyzer from the continuous ion beam leaving the ion source. One of the main advantages of this TOF instrumentation is high sensitivity as most ions that are pulsed into the analyzer eventually reach the detector. Other advantages are the ability to achieve very rapid data acquisition and to overcome spectral bias (see below), essential features of instruments producing GC peak widths of the order of milliseconds.

## **Instrument Operation**

One of the most important aspects of setting up a GC-MS system is proper temperature control of the various areas through which the sample passes. The injector and column are operated as with conventional gas chromatography but, then, care must be taken to preserve chromatographic integrity until the sample reaches the mass spectrometer. For most samples, the transfer lines (and separator, if used) should ideally be set to a temperature slightly higher than that of the upper column temperature limit to avoid condensation problems. The ion source should be similarly heated. In practice, however, it is found that a somewhat lower (20–30°C) transfer line temperature can be tolerated although this is, to some extent, sample dependent. The optimum temperature may need to be determined experimentally for a particular analysis and may be a compromise between the need to avoid condensation and to prevent thermal decomposition. Also of great importance in transfer line design is the need to avoid dead volumes where remixing of the separated sample constituents can occur. However, in most modern systems, the separation column can simply be inserted directly into the mass spectrometer ion source, thus overcoming problems associated with separate connections.

Once the sample has reached the ion source, it may be ionized using either EI or CI. EI gives extensive fragmentation and is the most appropriate method for structure determination and for producing spectra suitable for library searching. CI, which is a softer ionization technique, produces little fragmentation and is normally used when molecular ion assignment is in doubt. The presence of residual carrier gas does not significantly affect the spectrum under EI conditions, but must be taken into account with the higher ion source pressures encountered under CI conditions. The helium signal can be avoided simply by using a mass greater than 4 as the lowest scanned

mass in the spectrum. In practice, the spectrometer is usually operated with a lower mass value of  $\sim 50$  to avoid the additional abundant ion peaks from atmospheric gases present as the result of small leaks.

The scan speed of the mass spectrometer should be adjusted to give at least 5–6 scans over a typical GC peak in order to provide a usable peak profile. However, more scans will lead to a better definition of the peak profile and will be necessary for quantitative work where better peak shape definition is required. However, a compromise should be sought in order to avoid excessively large data files. For temperature-programmed work with capillary columns, scan speeds in the 0.1–1.0 s range are appropriate. If isothermal conditions are employed, the scan speed can be decreased during later stages of an analysis to accommodate the resulting broader peaks. However, for mixture analysis, temperature programming is recommended. For packed columns, slower scan speeds (typically 1–2 s) are appropriate. It must be recalled that, as the concentration of sample entering the ion source varies with time, single spectra will contain a concentration bias depending on which side of the GC peak the spectrum was acquired and in which direction (high to low mass or vice versa) the scan was taken. Spectra with the least bias are acquired at the peak top. Alternatively, bias can be minimized by averaging, with the aid of the data system, the several spectra acquired over the GC peak, assuming, of course, that only one component is present.

## **Processing GC-MS Data**

When first introduced, GC-MS equipment was not supplied with a data system as suitable computers had not been developed. Spectra were recorded on UV chart paper with the operator initiating the scan in response to a peak appearing on the GC trace. Now, all spectral acquisition and processing are data-system-dependent. The major function of the GC-MS data system is to digitize the analog output from the mass spectrometer detector and to perform a time-to-mass conversion to produce the mass spectrum. The digitization rate should be set to a value that gives  $\sim 10$ –20 sample periods over each ion peak in the spectrum. This sampling rate will depend on the mass spectrometer resolution and is usually set automatically once the resolution is specified. Various filters can then be set to remove noise and accommodate multiplet ion peaks. The most common filters are the position of the baseline and the requirement that a certain number of successive samples exceed the baseline value before the signal is

determined to be from a GC peak. The computer then calculates the peak centroid to produce the  $m/z$  value and stores this on disk together with the peak intensity. These data can then be further processed by the data system to produce spectral plots, various reconstructed chromatograms, or library searches.

### Ion Chromatograms

A plot of total ion current (TIC), the sum of all ion peak intensities in a spectrum, against time (or scan number) gives a chromatogram comparable to that obtained by GC using a conventional detector. However, chromatographic peak abundances will vary for compounds of different structure because of their different ionization efficiencies in the spectrometer. This difference in response factors applies to both EI and CI data. For example, under EI conditions, the signal recorded for hydrocarbons will be much weaker in a TIC than that recorded with a flame-ionization detector, relative to other compounds, because these compounds lack a heteroatom or unsaturation and are, thus, difficult to ionize.

The plot of the intensity of the  $m/z$  value of a single ion with time provides an accurate method for locating specific compounds in a chromatogram, particularly when they occur as components of an unresolved GC peak. Thus, chromatograms of the mass of a selected molecular ion can be used to identify candidate chromatographic peaks for a particular molecule, and chromatograms of the mass of a specific fragment ion can indicate which peaks in the TIC are produced by compounds with a given structural feature (Figure 2). It must, however, be borne in mind that false positives are possible. These can occur, for example, from the presence of an ion at the selected mass formed from a different fragmentation pathway or an ion present as an isotopic peak from an ion at a lower  $m/z$  value. This method, however, although giving a result similar to the peak profiles obtained by selected ion recording (see below), does not have the sensitivity advantage of the latter technique. It does allow, however, for retrospective ion plotting.

Chromatograms derived from combinations of several ions may also be plotted. These ions may be from a single compound, thus adding confidence to the assignment of structure, or they can be common to a group of compounds with similar structures. A variation on this theme is to use ions whose mass separation and relative abundance are characteristic of the presence of a given isotopic profile such as those given by chlorine-containing compounds. Another technique is to use only ions above a given mass for compounds that produce ions mainly in the

**Figure 2** (Top trace) TIC plot of the TMS derivatives of metabolites of  $\Delta^9$ -tetrahydrocannabinol extracted from mouse liver. Metabolites appear in scans 160–360, fatty acids in scans 0–160, and bile acids in scans 360–480. (Lower trace) Single ion plot of the ion at  $m/z$  145, diagnostic for hydroxylation at a specific site in the drug molecule. The metabolites producing peaks in the region of scans 250–320 contain this structural feature, while the other metabolite-related peaks do not. However, the ion is also present in the spectra of the fatty acids but not in those of the bile acids. The separation used a 2 m SE-30 packed column with a temperature-programmed run ( $2^\circ \text{ min}^{-1}$ ).

upper-mass range. In this way, many of the undiagnostic, low-mass ions leading to high backgrounds in the chromatograms may be removed.

### Deconvolution of Unresolved GC Peaks

Methods for peak deconvolution usually rely on detecting changes in mass spectral ion abundances from the individual components as they elute across the peak. The Biller–Biemann and similar algorithms, for example, look at each spectrum and set a flag against all ions whose intensity is greater than that in adjacent spectra. This essentially marks the top of the GC peak corresponding to the compound containing the flagged ions. By plotting chromatograms from only flagged ions, a much-improved chromatogram can be obtained (Figure 3). Spectra of individual components can also be obtained by using only the flagged ions. A disadvantage of these algorithms is that, for successful deconvolution, the spectra must possess ions of different mass and these must pass through an intensity maximum in different scans. Recently, more sophisticated deconvolution techniques such as those based on maximum entropy algorithms have been introduced.

### Spectrum Addition and Subtraction

Spectral addition enables all the spectra acquired from a given GC peak to be averaged, with the result that a greater signal-to-noise ratio is obtained and

**Figure 3** The TIC trace from **Figure 2** processed by flagging ions in the scans in which their intensity maximizes and ignoring ions below  $m/z$  300. Several of the peaks eluting in the region of scans 250 and 310 have been resolved into several components. One of the components of two of these resolved peaks, which can be seen as a shoulder in **Figure 2**, contains the ion at  $m/z$  145.

much less bias is present. Spectral subtraction can be used, either to remove background or to subtract ions from a given compound from a mixed spectrum. Most data systems now allow an almost unlimited selection of peaks to be either added to or subtracted from each other.

### Library Searching

Library searching is invaluable for the rapid identification of sample constituents and can often give clues to the identity of unknown compounds. Several commercial libraries are available containing many tens of thousands of spectra. Among the largest are the Wiley Registry of Mass Spectral Data 7th Edition (390 000 spectra) and the NIST/EPA/NIH Mass Spectral Library (129 000 spectra). Several search algorithms are available, of which the so-called reverse search involving finding the peaks from the library spectrum in the spectrum of interest is probably the most useful. To avoid searching the entire library for each compound, it is common practice to limit searches to, for example, compounds below a certain mass or to compounds with specific structures. Best-fit spectra are usually presented to the analyst, together with a goodness-of-fit factor for evaluation. However, it is important to realize that the best library match may not be the correct molecular identity. More confidence in a correct match can be gained by making use of the compound's retention index, another parameter that can be incorporated into databases.

### Calculation of Elemental Composition

Where spectra have been acquired under high-resolution conditions and ionic masses measured to a few parts per million, the data system can be used to calculate possible elemental compositions that fit the observed mass to within a specified mass window. Again, upper limits to the elements present must be provided to avoid the production of an excess of redundant data.

### Quantitative Measurements

#### Selected Ion Monitoring

Selected ion monitoring (SIM) is a major application for GC-MS and allows the instrument to be used in its most sensitive mode for quantitative measurements. SIM was first introduced in the 1960s by Hammar and co-workers under the name mass fragmentography and has acquired a number of other names such as multiple ion monitoring (or recording) over the years. It owes its high sensitivity to the method of focusing the mass spectrometer. The instrument is focused on only a few ions that are recorded continuously rather than operated in the normal scanning mode. In its most sensitive mode, one ion is monitored for the duration of the experiment. Consequently, all the current from this ion is captured, whereas if the mass spectrometer were scanned only a small fraction of the ions at this  $m/z$  value would be acquired. Obviously, this method has reduced selectivity compared with that of scanning the whole spectrum, but selectivity can be partially restored by continually jumping between several significant ions, recording their ion current for a few milliseconds and then reconstructing the ion profiles.

The technique is most conveniently implemented with a quadrupole instrument as mass changes can be accomplished very rapidly. Channel switching by changing the magnetic field of a magnetic sector instrument is slower because of hysteresis effects. More rapid switching is usually achieved with sector instruments by altering the accelerating voltage, but at the expense of a reduction in sensitivity for ions with higher  $m/z$  values (focused at lower acceleration potentials) and some defocusing of the ion source.

Sensitivity in mass spectrometry is determined by the signal-to-noise ratio, which, in turn, has components of instrumental and chemical noise, the latter arising from the sample. Instrumental noise is generally a fixed parameter, but chemical noise can often be reduced by the user, not only by more efficient sample cleanup but by the way in which the instrument is operated. One such method is the technique of selected reaction monitoring, implemented on

sector or tandem mass spectrometers, whereby both parent and fragment ions are selected, thus ensuring that the monitored fragment ion arises from a specific precursor. Such an experiment could be set up with a triple quadrupole mass spectrometer by using the first quadrupole to select the parent ion and then monitoring the product or products of fragmentation with the analyzing quadrupole. Although the ion current of the monitored ion(s) is lower than that of the parent, this can be more than compensated for by a great reduction in the chemical noise.

For quantitative measurements, the 'ion-jumping' techniques allow variants of the analyte labeled with stable isotopes to be used as internal standards. The instrument can be set to record one or more ions from the analyte together with the corresponding ions from the internal standard (Figure 4). As the

**Figure 4** Selected ion monitoring for the quantification of a drug in human plasma using an internal standard labeled with 12 deuterium atoms. The molecular ions are recorded with the channels labeled  $m/z$  425 and 437 for the drug and internal standard, respectively, and the  $[M - CH_3]^+$  ions are recorded at  $m/z$  410 and 419. Note that three deuterium atoms are missing from the  $[M - CH_3]^+$  ion. The second set of peaks is from endogenous cytidine, which contains ions at the same mass as the analyte and emphasizes the importance of ensuring separation of analyte from contaminating compounds and of using both retention time and peak intensity in these measurements.

standard is, to a first approximation, chemically equivalent to the analyte, extraction and derivatization losses during sample preparation are compensated for and high accuracy and precision are obtained. Care must however, be taken to ensure that the isotopically labeled standard has a sufficient mass difference from the analyte to avoid interference by the latter's natural isotopes, and that no unlabeled material is present in the standard. Where interference is experienced, nonlinear calibration curves are obtained, which require special treatment to restore accuracy. Several such methods have been described in the literature but none appears to be universally valid.

Quantification by SIM can also be accomplished using nonlabeled standards. If a chromatographic separation exists between the standard and analyte, monitoring can take place by recording a common ion; this allows the technique to be used in its most sensitive mode. The most common nonlabeled standards are homologs of the analyte, but other chemically similar compounds can also be used, although sometimes at the expense of some accuracy.

#### Use of GC-MS for Trace Analysis

Trace analysis requires the highest sensitivity and is usually accomplished either by increasing the mass spectrometer resolution (a double focusing magnetic instrument is required) or by using MS/MS techniques. Both methods increase the selectivity of detection and improve the signal-to-noise ratio rather than by increasing the absolute signal amplitude. The first method makes use of the fact that ions appearing at a given nominal  $m/z$  value will frequently have different compositions and, thus, different absolute masses. By increasing the instrument resolution to such a value that these ion peaks are resolved, and monitoring only the ion of the specific composition required, most of the interfering compounds can be rejected. A good example of this is in dioxin analysis, where several other chlorinated aromatic compounds have the same nominal but different accurate masses. By monitoring only the absolute mass of the dioxin molecule ( $m/z$  321.8936), the interfering compounds can be rejected.

In the MS/MS methods, an ion from the analyte is selected early in its path through the instrument, fragmented in a collision cell, and selected product ions are monitored. This procedure is most easily accomplished with a tandem, hybrid, or triple quadrupole instrument and ensures that the ions monitored have originated from a specific precursor ion rather than from any other compound that has the same GC retention time.

## Sample Preparation

For successful GC–MS analysis, the sample must be both volatile and thermally stable. Few organic compounds fulfill these criteria as they possess polar or reactive functional groups that have a detrimental effect on these properties. Protecting these functional groups by derivatization is the normal method for conferring good GC–MS behavior. Suitable derivatives are listed in **Table 1**.

Although the derivatives used for GC analysis are generally suitable for conferring volatility, not all derivatives give ideal mass spectra. A good example of this is given by the methyl and trimethylsilyl (TMS) esters of fatty acids. The mass spectra of these derivatives give very little information on the alkyl chain structure, as fragmentation is dominated by cleavages around the carboxylic ester group (**Figure 5**).

A better derivative is the picolinyl ester. This derivative, under EI, acquires a positive charge on the nitrogen atom rather than on the ester oxygen atoms. The stability of the pyridine ring prevents fragmentation near the charge site, but causes the nitrogen atom to act as a proton acceptor and to abstract a proton from various positions of the alkyl chain to

leave a radical site. The chain then fragments by radical-induced cleavage in modes that reveal the chain structure (**Figure 6**).

Another use for derivatization in quantitative GC–MS work is to produce spectra in which much of the ion current is diverted into a single ion in order to give high sensitivity for selected ion monitoring studies. Good derivatives for this purpose are those that contain the *tert*-butyldimethylsilyl (TBDMS) group. This derivative fragments preferentially by loss of the *tert*-butyl radical to give a very abundant ion at  $[M - 57]^+$  (**Figure 7**).

Derivatives used for GC–MS should preferably be simple to prepare and form in quantitative yield. Most of those listed in **Table 1** fulfill these criteria. In some cases, such as with the TMS ethers, preparation consists of little more than dissolving the sample in the reagent, possibly with heating, and direct injection of the mixture into the chromatograph.

Sample volumes should be in the 0.1–2  $\mu$ l range, with  $\sim 10$ –1000 ng being optimum for the acquisition of scanned spectra. Although intuitively obvious, it should be emphasized that samples should be prepared in sample vials of the appropriate size for holding 10–100  $\mu$ l of solution, of which many can be

**Table 1** Derivatives suitable for GC–MS

Functional group	Derivative	Comments
Hydroxyl	TMS ether	Good GC and MS properties
	TBDMS ether	$[M - 57]^+$ ion for high sensitivity, longer retention time than TMS
	Methyl ether	Good GC and MS properties. Not as easy to prepare as TMS
	Higher alkyl	Used as GC shift reagents (reagents used to alter the retention time of selected compounds).
	Acetyl	Easy to prepare. Sometimes relatively large increases in GC retention time
<i>cis</i> -Diol	Cyclic alkane boronate	Low mass increment
	Cyclic acetal	
Carboxylic acid	Methyl ester	Good GC performance. Relatively poor MS fragmentation
	TMS ester	Slightly acid labile
	Nitrogen-containing, e.g., pyridine	Good for structural studies of long-chain compounds
Amine	Acyl	Good
	Perfuroacyl	Good electron-capturing properties for high sensitivity negative ion detection
	Schiff bases	Less stable than TMS ethers of alcohols
	TMS	
Carbonyl	Alkyloxime	Can give two GC peaks ( <i>syn</i> and <i>anti</i> )
	Schiff bases	
Phosphate	TMS	Spectra contain many rearrangement ions, e.g., $m/z$ 299
	Methyl ester	More stable than TMS derivatives
Sulfate	Unstable	Usually detected by replacement following derivatization of other functional groups to give a mixed derivative such as TMS/acetyl

**Figure 5** EI (70 eV) mass spectrum of the TMS derivative of octadecanoic (stearic) acid. The four ions at  $m/z$  117, 129, 132, and 145 are a characteristic feature of the TMS derivatives of fatty acids, but there are few ions that provide information on the structure of the aliphatic chain.

**Figure 6** EI (70 eV) mass spectrum of the picolinyl ester of 14-methyloctadecanoic acid. Abstraction of a proton from different positions of the aliphatic chain produces radical sites that induce chain cleavage. The position of the methyl group is revealed by the absence of the even-mass ion at  $m/z$  318 and the relatively high abundance of the ions at  $m/z$  304 and 332.

obtained commercially. Sample vials made for autosamplers containing an insert with a small capacity are ideal. The large (10 ml) sample tubes that are frequently used for sample preparation should be avoided as containers for the final sample solution because the small volume of solvent appropriate for the sample will evaporate into the large container volume, causing loss of control over the sample concentration. Where larger volumes of solvent have been used during work-up and subsequently evaporated, the sample should be transferred to a small sample vial before analysis.

Plastic apparatus is also to be avoided when organic solvents are involved as plasticizers are easily leached out of such materials by the solvent and, after concentration of the sample, yield spectra that frequently mask that from the analyte. Dialkyl phthalates are the plasticizers most commonly encountered and can be recognized by their production

of major ions at  $m/z$  149 and 167. Teflon is free from this problem and is frequently used as a liner for the closures of sample vials. Polypropylene microcentrifuge tubes also appear to be relatively free from phthalates and are finding increased use in GC-MS work. Commercial solvents very often contain traces of these and related compounds that can become problematical after sample concentration. Thus, all solvents used for extraction should be redistilled before use.

With very low concentrations of analyte, adsorption onto glass surfaces becomes a problem. This problem is best avoided by silanizing the glassware before use. A suitable method is to soak the glass in a 10% solution of dichlorodimethylsilane in toluene for  $\sim 1$  h, rinse with dry toluene and then with methanol. The silane forms dimethylsilyl bridges between adjacent hydroxyl groups on the glass surface, and the methanol converts the chlorine atom of

**Figure 7** Effect of derivatization on the 25 eV EI mass spectral fragmentation of 3 $\beta$ -hydroxy-5 $\alpha$ -androstan-17-one: (top) TMS derivative; (centre) methoxydimethylsilyl derivative showing more extensive fragmentation; (bottom) *tert*-butyldimethylsilyl derivative with a large  $[M - 57]^+$  ion suitable for high-sensitivity monitoring.

dimethylsilane groups that are bonded to only one oxygen atom into a methoxy group. Deactivated glass sample vials are now available commercially.

## Use of Stable Isotopes

In addition to their use as internal standards, compounds labeled with stable isotopes have numerous other uses in GC-MS. Thus, the numbers of functional groups in a molecule can be determined by measuring the mass difference between two portions of the sample that have been derivatized with an unlabeled and a labeled reagent. TMS and [ $^2\text{H}_9$ ]TMS derivatives are particularly useful for hydroxyl and carboxyl groups. Where a derivative such as TMS, which reacts with different functional groups (i.e., alcohols, carboxylic acids, etc.), has been used, the preparation of group-specific derivatives such as methyl esters can subsequently be used to differentiate them. Another example is use of the isotope doublet technique in cases where it is not easy to identify sample (e.g., drug)-related peaks in the TIC from peaks produced by endogenous compounds. This technique involves the use of a 1:1 mixture of the

drug and a labeled variant as the test substance and to search the resulting GC profile for spectra containing doublet peaks. An example is shown in Figure 8.

Finally, stable isotopes are frequently used in clinical studies, where their main advantage over radioactive isotopes is that they present no hazard to the patient and can be used quite safely in children. Many applications have been published such as their use to monitor the pharmacokinetics of a single dose of drug during chronic therapy or to measure the bioavailability of a drug from various formulations.

## Future Trends

GC-MS has reached the state of a mature technique and one that the use of modern data systems has made relatively easy to use. Further increases in sensitivity are always welcome and are currently being addressed by the use of TOF instruments. High sensitivity, in turn, allows narrower GC columns with higher resolution and shorter run times to be used. It is probable that the recent introduction of TOF instrumentation into this field will lead to the

advancement of the technique for the analysis of even smaller amounts of material in shorter times than is currently possible.

Knowing the identity of each component in a mixture is necessary for many analytical-scale separations, and simply measuring retention data for this purpose is often too ambiguous for the identification of molecules eluting from a capillary gas chromatography (GC) column, which has the capability of resolving several hundred components. Prior knowledge about the chemical structure of the components and spiking of the mixture with one or more reference standards may aid the identification process; however, a less ambiguous identification can be accomplished by interfacing the chromatograph to a sensitive, rapid-scanning spectrometer to obtain unique signatures of each component. This instrument should allow each component to be detected in real time without any loss in chromatographic resolution. Mass spectrometry (MS) is the most commonly applied technique for this purpose, but it has certain limitations, in particular for distinguishing between structural isomers, such as *ortho*-, *meta*-, and *para*-xylene, whose electron-impact and chemical-ionization mass spectra are identical. For such molecules a complementary technique to MS is desired. Fourier transform infrared (FTIR) spectrometry, which yields unique spectra for most structural isomers, has frequently been used as an alternative technique for this purpose.

## Light-Pipe-Based GC–IR Instruments

### Measurement of the Spectrum

The coupling of gas chromatographs and FTIR spectrometers (GC–FTIR) has been accomplished by three approaches. In the first, and by far the simplest, the GC column is connected directly to a heated flow-through cell. For capillary GC, this cell is usually fabricated from a 10-cm length of heated glass tubing with an internal diameter of  $\sim 1$  mm. The inside bore of this tube is coated with a thick enough film of gold to be highly reflective to infrared radiation. Infrared-transparent windows (such as potassium bromide) are attached to both ends of the tube. Infrared radiation entering one window is multiply reflected down the gold-coated interior bore before emerging from the other window, giving rise to the name *light-pipe* for this device. The effluent from the GC column is passed into one end of the tube and out of the other via heated fused-silica transfer lines. The entire unit is held at a temperature between 250 and 300°C to preclude the condensation of semivolatile materials.

Infrared radiation from an incandescent source, such as an SiC Globar, is collimated and passed through a rapid-scanning interferometer so that each wavelength in the spectrum is modulated at a different frequency. The beam of radiation is then focused onto the first window of the light-pipe and the infrared beam emerging from the second window is refocused onto a sensitive detector (typically a liquid-nitrogen-cooled mercury cadmium telluride (MCT) photoconductive detector). A typical system is

Fourier transform infrared (FTIR) spectrometry, which yields unique spectra for most structural isomers, has frequently been used as an alternative technique for this purpose.

## Light-Pipe-Based GC-IR Instruments

### Measurement of the Spectrum

The coupling of gas chromatographs and FTIR spectrometers (GC-FTIR) has been accomplished by three approaches. In the first, and by far the simplest, the GC column is connected directly to a heated flow-through cell. For capillary GC, this cell is usually fabricated from a 10-cm length of heated glass tubing with an internal diameter of ~1 mm. The inside bore of this tube is coated with a thick enough film of gold to be highly reflective to infrared radiation. Infrared-transparent windows (such as potassium bromide) are attached to both ends of the tube. Infrared radiation entering one window is multiply reflected down the gold-coated interior bore before emerging from the other window, giving rise to the name *light-pipe* for this device. The effluent from the GC column is passed into one end of the tube and out of the other via heated fused-silica transfer lines. The entire unit is held at a temperature between 250 and 300°C to preclude the condensation of semivolatile materials.

Infrared radiation from an incandescent source, such as an SiC Globar, is collimated and passed through a rapid-scanning interferometer so that each wavelength in the spectrum is modulated at a different frequency. The beam of radiation is then focused onto the first window of the light-pipe and the infrared beam emerging from the second window is refocused onto a sensitive detector (typically a liquid-nitrogen-cooled mercury cadmium telluride (MCT) photoconductive detector). A typical system is

**Figure 1** Schematic of typical light-pipe-based GC-FTIR interface (based on Hewlett Packard IRD).

illustrated schematically in **Figure 1**. The signal measured in this way is known as an *interferogram* and the Fourier transform of the interferogram yields a single-beam spectrum. By calculating the ratio of a single-beam spectrum measured when a component is present in the light-pipe to one measured when only the helium carrier gas is present, the transmittance spectrum,  $T(\nu)$ , of the component is obtained. The transmittance spectrum is usually converted to absorbance,  $A(\nu)$ , immediately by the standard Beer's law operation,  $A(\nu) = -\log_{10} T(\nu)$ , as the relative intensities of bands in absorbance spectra are independent of the concentration of the analyte, thereby allowing spectral library searching (*vide infra*) to be performed. For light-pipe-based GC-FTIR systems, it is rarely necessary to measure spectra at high resolution, as the spectral bands are quite broad. Since most bands in the spectra of molecules in the vapour phase have a width of at least  $10 \text{ cm}^{-1}$ , the typical resolution at which GC-FTIR spectra are measured is  $8 \text{ cm}^{-1}$ .

When operated at their highest scan speeds, FTIR spectrometers can measure between 5 and 20 interferograms per second that would yield spectra of this resolution. During a chromatographic analysis, interferograms are measured continuously. Thus for a 30-minute-long chromatogram, it would be possible to measure tens of thousands of interferograms, giving rise to an amount of data that would be too great to store on a disk on a typical personal computer (PC). Fortunately, most GC peaks have a full-width at half-height (FWHH) of several seconds. Thus it is common practice to average blocks of interferograms for a period of time that is slightly less than the FWHH of the narrowest peak in the chromatogram (usually 1–2 s). The single-beam spectrum is then computed from this signal-averaged

interferogram and ratioed against an appropriate background spectrum; finally, the resulting transmittance spectrum is converted to a linear absorbance format. On contemporary PCs this entire sequence of operations is performed while the next block of interferograms is being acquired.

### Reconstruction of Chromatograms

The end result of this process is that over 1000 absorbance spectra, corresponding to the contents of the light-pipe measured at  $\sim 1$ -second intervals throughout the entire chromatogram, are stored at the end of the run. Many of these spectra contain no useful information as they were measured when no component was present in the light-pipe; thus, the next step in a GC-FTIR analysis is to determine which of the stored spectra contain useful information. To achieve this, a chromatogram must be reconstructed from the spectroscopic data. This is usually achieved in two ways, the first of which is known as the *Gram-Schmidt* (GS) vector orthogonalization method. Here, short, information-rich regions of the interferograms are treated as vectors, and the vector distance between this part of each interferogram measured during the chromatographic run and several interferograms that were acquired when nothing except the helium carrier gas was flowing through the light-pipe (known as the basis set) is calculated. When an analyte elutes from the column, the magnitude of the vector difference is approximately proportional to the quantity of this material in the light-pipe. Because only a short region of the interferogram is examined, calculation of the GS 'signal' can be achieved in a few milliseconds. Furthermore, since all compounds besides monatomic and homonuclear diatomic molecules have at least one band in their infrared spectrum, GS chromatograms are very nonselective. Some compounds yield much stronger infrared spectra than others, however. For example, the spectra of most nonpolar compounds are rather weak, whereas the spectra of very polar compounds are usually much stronger. As an example, the detection limits for GS chromatograms of polycyclic aromatic hydrocarbons (which have very low absorptivities over most of their infrared spectra) are  $\sim 20$  times greater than the corresponding values for the barbiturates (which are very polar and have several strong infrared absorption bands in their spectra).

The other commonly used algorithm by which chromatograms are constructed from the infrared data involves calculating the integrated absorbance in one or more specified spectral regions. These regions are usually chosen to correspond to the

characteristic absorption frequencies of the functional group present in the class(es) of molecules of interest. The chromatograms generated by this approach have been called by a variety of names, including Chemigrams<sup>TM</sup>, functional group (FG) chromatograms and selective wavelength (SW) chromatograms. FG chromatograms are, of course, far more selective than GS chromatograms, but are rarely completely selective as many molecules have weak overtone and combination bands over much of the fingerprint region of the infrared spectrum. For compounds with functional groups giving rise to intense absorption bands, such as the C=O stretching mode of carbonyl compounds, the limits of detection of FG chromatograms may be less than those of the corresponding GS chromatograms, but the two algorithms often have comparable sensitivity. A useful way to detect the presence of a particular functional group is to compare the relative heights of peaks in the GS and FG chromatograms. If the ratio of the peak heights in the FG and GS chromatograms is large, the presence of that functional group in that component is indicated; if the ratio is small, there is a much smaller probability that the analyte contains that functional group.

### Spectral Searching

Once the chromatography has been completed, the spectra of those components of interest can be displayed. (In fact, several GC-FTIR software packages allow the spectra to be displayed even while data acquisition is still in progress.) Each component generating a peak in the GS chromatogram with a signal-to-noise ratio greater than  $\sim 10$  can usually be identified by comparing its spectrum to a library of vapor-phase reference spectra. The unknown and reference spectra are first scaled so that the most intense band in each spectrum has the same absorbance (usually 1.0). By treating the spectra as vectors, the Euclidean distance between the unknown and each reference spectrum is calculated. This distance is usually called the *hit quality index* (HQI); the smaller the HQI, the better the spectral match. The highest probability for the identification of the unknown is that of the compound in the reference library yielding the smallest HQI. However, unequivocal identifications cannot be made on this basis alone, for several reasons. The reference spectrum of the authentic analyte may not be present in the spectral library. If the spectrum of the unknown is noisy, the value of the HQI may be determined more by noise than by the true absorption spectrum. The reference spectrum may have been measured with the sample at a different temperature from the light-pipe, measured

at a slightly different resolution, or computed with a different apodization function. Finally, some members of homologous series can have very similar spectra, so it is not uncommon for compounds of the same type (e.g., methacrylate esters) to give similar HQI values.

It is always recommended that the user should make a side-by-side comparison of the GC-IR spectrum and the reference spectra of the top few 'hits' to get a good idea of the probability that the structure of the analyte is best represented by the structure of the top hit, or by one of the other close hits, or whether there is enough similarity between the GC-IR spectrum and all of the closely matching reference spectra that unequivocal identification is impossible. In this case, the simultaneous application of mass spectrometry may be necessary to yield an unequivocal identification.

### Limits of Detection and Identification

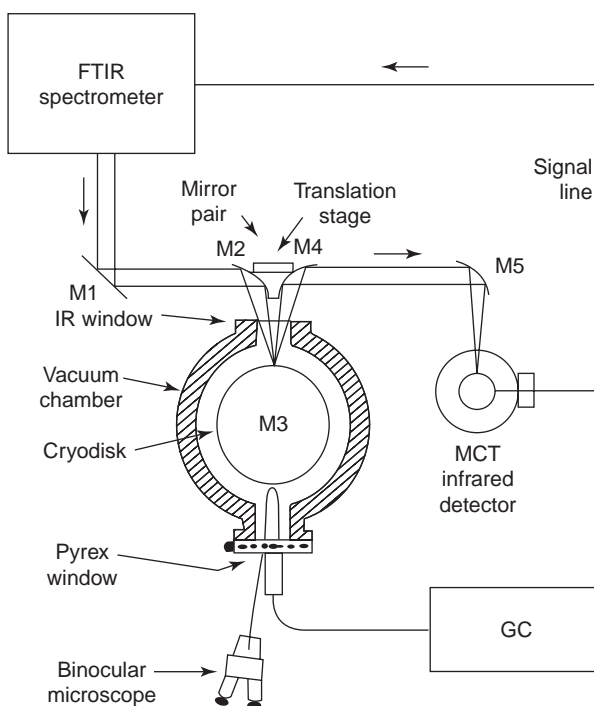

The limit of detection (LOD) for an acceptable GC-IR response for most compounds is between about 1 and 20 ng (injected) per component, the actual value depending on the chemical nature of the analyte. The LOD is often defined with respect to the strongest band in the spectrum. Most bands in the infrared spectrum of nonpolar compounds are fairly weak and so these compounds tend to have the highest LODs, but even these compounds usually have at least one band in the spectrum with a high absorptivity. Examples include the C-H stretching bands of alkanes and the aromatic C-H out-of-plane deformation bands of polycyclic aromatic hydrocarbons. Detection limits also depend on the width of the GC peak; the wider the peak, the more dilute the analyte and the higher the LOD.

The amount of a given component that must be injected into the chromatograph to yield an identifiable spectrum, often known as the minimum identifiable quantity (MIQ), depends not on the *strongest* band, but on the signal-to-noise ratio of the *most characteristic bands* in the spectrum. For an analyte with a spectrum that is very different from any other spectrum in the reference database, the MIQ may be only slightly higher than the LOD. On the other hand, there are often only very subtle differences between the spectra of members of this class of compounds. If the analyte is a member of a homologous series and several reference spectra of members of this series are contained in the library, the signal-to-noise ratio of the spectrum must be high, and hence the MIQ will be much greater than the LOD if the analyte is to be correctly identified.

If a minor peak is present in a chromatogram measured with a conventional GC detector such as a flame ionization detector (FID), but is not observable in the GS or FG chromatogram, it may be possible simply to inject a greater volume of the sample into the chromatograph. Even if the major components overload the GC column in this case, the minor components will not. However, sometimes the major peaks will broaden to the point that they start to overlap a neighboring minor peak. In this case, it may become necessary to subtract the spectrum of the major peak (linear in absorbance) from the spectrum measured in the region of the minor peak, to identify the minor component. This procedure is needed because of the relatively low sensitivity of light-pipe-based GC-IR instruments. Two other approaches have been described that have led to increased sensitivity for GC-IR measurements, and are described below.

### Matrix-Isolation GC-IR

In the first of these, argon is mixed with the helium mobile phase, either as a minor ( $\sim 1\%$ ) component in the carrier gas or by addition at the end of the GC column. The column effluent is then sprayed from a heated fused-silica transfer line onto a rotating gold-plated disk that is maintained at a temperature of less than 15 K. Helium does not condense at this temperature but argon does. By locating the end of the transfer line an appropriate distance from the cooled disk, argon is deposited as a track  $\sim 300\ \mu\text{m}$  in width. Any component emerging from the transfer line at the same time is trapped in the argon matrix. After the separation has been completed, the disk is rotated to a position where the focused beam from an FTIR spectrometer is transmitted through the track of argon, reflects from the gold-coated disk, passes again through the argon and then is collected and focused on to an MCT detector, as shown in Figure 2. In principle, if the concentration of any analyte in the argon matrix is low enough, each analyte molecule will be isolated from like molecules by the argon matrix. Despite the fact that the concentration is usually a little too high for true matrix isolation to be achieved in GC-IR measurements, this technique none the less is known as *matrix isolation GC-IR*. By rotating the disk slowly, a series of spectra can be measured that is analogous to the series of spectra that is measured in real time during a light-pipe-based GC-IR run and either GS or FG chromatograms can be constructed from these data. Each component may be identified by spectral library searching, but a special library of spectra of matrix-isolated standards is required.

**Figure 2** Schematic of matrix isolation GC-FTIR interface (based on Mattson Instruments Cryolect).

The advantages of matrix isolation are based on the following considerations. First, the width of the track is  $\sim 300\ \mu\text{m}$ , compared with 1 mm for the diameter of a light-pipe. Thus, the sample is more concentrated over the cross-sectional area of the IR beam and a given amount of sample will yield a spectrum with more intense absorption bands. Second, because each component is trapped on the disk, it is common practice when minor components are to be identified by matrix isolation GC-IR to signal-average interferograms for several minutes with the disk stationary, enabling a significant increase in sensitivity to be achieved over real-time measurements. A final advantage that has been claimed for matrix-isolation GC-IR measurements is the increase in the absorptivity at the peak of each band in the spectrum because of the decrease in bandwidth that occurs on matrix isolation (the band area remaining approximately constant). This is true for small molecules, but large molecules disrupt the crystal structure of the argon to such an extent that a certain amount of molecular motion is possible. As a result, the widths of many bands in the spectra of large asymmetric molecules prepared in this way are surprisingly similar to widths of corresponding bands in the spectra of the corresponding molecules prepared as KBr disks.

The exception to this behavior is observed in the spectra of compounds that contain O-H or N-H

groups. In the crystalline form of such compounds, the O–H and N–H groups are strongly intermolecularly hydrogen bonded. As a consequence, the O–H and N–H stretching bands in their KBr-disk spectra are exceptionally broad, often having a width of several hundred wavenumbers. When these molecules are isolated in an argon matrix, however, no intermolecular hydrogen bonding takes place, and the O–H and N–H stretching bands appear as very narrow spectral features. Thus, when the spectra of matrix-isolated species such as alcohols, phenols, or amines are measured at high resolution, excellent specificity is often gained by matrix isolation GC–FTIR.

The major problem with this approach to GC–IR (which can to a certain extent be shared with vapor-phase measurements) is the lack of extensive libraries of appropriate reference spectra. This disadvantage has largely been overcome by the final type of GC–IR interface to be described below.

### Direct Deposition GC–IR

In the remaining approach to GC–FTIR, the effluent from the column is directed at a slowly moving, cooled window mounted on a computer-controlled  $x$ – $y$  stage. Zinc selenide cooled to the temperature of liquid nitrogen is the most commonly used substrate. Each eluting component is deposited on the window as a very narrow spot. In the commercially available form of this interface, shown in Figure 3, the typical width of each spot is  $\sim 100\text{ }\mu\text{m}$ . The stage moves so that each deposited component passes through the beam focus of an infrared microspectrometer shortly after deposition. As for light-pipe-based GC–IR systems, spectra are measured continuously throughout

the chromatographic run and GS and/or FG chromatograms can be output in real time. This *direct deposition* approach for GC–IR has two important advantages over light-pipe or matrix-isolation GC–IR systems – it yields higher sensitivity and the measured spectra are very similar to reference spectra of standards prepared as KBr disks. Let us first recognize the reason for the increased sensitivity of direct deposition GC–IR measurements.

As seen in the previous section, the smaller the cross-sectional area of the sample, the greater the absorbance of all bands in the spectrum. Because the sample is contained in a  $100\text{-}\mu\text{m}$  diameter spot rather than a 1-mm diameter light-pipe, its cross-sectional area is 100 times less, so that bands will be  $\sim 100$  times more intense. To attain the optimal sensitivity, the diameter of the IR beam should be approximately equal to the width of the spot, i.e.,  $\sim 100\text{ }\mu\text{m}$ , and a detector of the same size should also be used. Several other optical factors should be included in the comparison, but in general it is found that the signal-to-noise ratio of GC–IR spectra measured online using the direct deposition technique is  $\sim 50$  times greater than the corresponding measurement made using a light-pipe system. The sensitivity advantage of direct-deposition GC–FTIR systems can be further increased by post-run signal averaging in a manner analogous to the matrix-isolation GC–IR system described above. If each real-time spectrum is measured over 1-second blocks, post-run averaging for just 1 min will yield an improvement in sensitivity of almost a factor of 8.

As noted above, the MIQ for direct deposition GC–IR measurements varies with the polarity of the analyte. The LOD for real-time measurements of several analytes by this technique was  $\sim 50\text{ pg}$ . When very polar analytes are injected, this number can be further reduced. For example, the LOD for several barbiturates was found to be  $\sim 13\text{ pg}$ . Spectra of these barbiturates in the high-wavenumber region measured by a light-pipe-based GC–FTIR instrument (Hewlett Packard IRD) and a direct-deposition system (Bio-Rad/Digilab Tracer) are shown in Figure 4. Differences between the vapor-phase and condensed-phase spectra of molecules that can exhibit strong intermolecular hydrogen bonding are readily apparent in this figure. For example, the sharp bands absorbing near  $3430\text{ cm}^{-1}$  in the vapor-phase spectra are due to the N–H stretching vibration of isolated (non-hydrogen-bonded) molecules. In the corresponding condensed-phase spectra measured by direct deposition GC–FTIR, the N–H stretching modes of the intermolecularly hydrogen-bonded barbiturates are seen as broad bands near  $3220$  and  $3110\text{ cm}^{-1}$ . Similar differences between vapor-phase

**Figure 3** Schematic of direct deposition GC–FTIR interface (based on Bio-Rad/Digilab Tracer).

**Figure 4** (A) Flow-cell and (B) direct-deposition GC-FTIR spectra of (a) barbital, (b) aprobarbital, (c) butabarbital, and (d) phenobarbital from 4000 to 2500  $\text{cm}^{-1}$ ; 12.5 ng and 375  $\mu\text{g}$  of each component were injected for the light-pipe and direct-deposition spectra, respectively.

**Figure 5** Low-wavenumber region of the spectra shown in Figure 4.

and condensed-phase spectra of barbiturates are also seen in the spectral region between 2000 and 1000  $\text{cm}^{-1}$  (see Figure 5). The difference between the sensitivity of the light-pipe and direct-deposition GC-FTIR measurements can be seen by comparing the noise levels of the spectra shown in Figure 4 and recognizing the fact that it required 30 times more of each barbiturate to be injected for the spectra measured using a light-pipe than by direct deposition.

On deposition, the molecules of a given analyte form randomly oriented crystallites on the zinc selenide window. These crystallites are similar to the crystallites that are formed on grinding of solid samples during the preparation of KBr disks or mineral-oil mulls. Not surprisingly, therefore, the spectra of compounds obtained by direct deposition GC-IR are very similar to the KBr-disk spectra of the

corresponding compounds. Extensive libraries (>150 000 entries) of reference spectra of standards prepared in this way are available commercially. The only compounds that cannot be readily identified in this manner are molecules with very strongly hydrogen-bonding groups or for analytes exhibiting polymorphism. For trace analytes containing O-H or N-H groups, the best results on library searching are usually found by examining only the spectral region below 2000  $\text{cm}^{-1}$  and eliminating the region containing the strong, broad O-H and N-H stretching modes from the search.

## Prognostication

On-line infrared spectrometry is proving to be an important way of identifying molecules eluting from

a gas chromatograph. Light-pipe-based systems are the simplest, least expensive and most reliable, but often prove to have inadequate sensitivity for the identification of minor components. Of the two deposition-based techniques, the direct deposition approach has limits of detection that rival those of benchtop GC–MS systems and has the great advantage of producing spectra that are directly comparable to KBr-disk reference spectra, of which there are over 150 000 available in digital form (i.e. suitable for computerized library searching). Thus one can forecast an increasing use of systems based on this principle in the future. It is also noteworthy that interfaces between FTIR spectrometers and both supercritical-fluid and liquid chromatographs based on the same principle have been described.

### Introduction

Nonanalytical applications of gas chromatography (GC) in the study of various phenomena in gases, solutions, and on solid surfaces are set out in **Figure 1**. They allow investigation of several phenomena in the same relatively simple apparatus, whereas other much more costly methods usually only permit the study of one such process.

The other main advantages of GC over static methods in investigating physicochemical phenomena are:

- GC is mainly used for examining very small samples at near-infinite dilution. Such concentrations can be applied directly to investigations of thermodynamic equilibrium.
- The accuracy of measurement of physicochemical phenomena by chromatography is at least as high as that of other methods, and the rate at which measurements can be made is much higher.
- Physicochemical properties may be measured over a wide range of temperature.

The accuracy of chromatographic results depends on whether a specific or relative retention volume,

retention time, or peak width or area is used for estimation. The accuracy is greatest for the retention time, lower for the peak width, and lowest of all for the peak area.

The precision of physicochemical measurements by GC relies on the ability of the instrument to control and measure all parameters relating to the chromatographic process. Sources of inaccuracy include the determination of stationary phase mass, column temperature and its gradients, flow rate and stability, pressure drop along the column, ‘dead space’ in the system, etc. Sophisticated computerized equipment allows precise measurement and control of all these operating parameters.

High purity of the carrier gas is essential, since even trace amounts of a contaminant that may be adsorbed will, as a result of accumulation, badly distort the results.

In analytical GC, particular emphasis is laid on the separation of the mixture into its components, which are recorded on the chromatogram as a series of peaks or steps. On the other hand, where GC is used as a physicochemical research tool, we are usually interested only in a single peak and how this alters with changes in the experimental conditions. The task is therefore to determine the effect of elementary processes taking place in the column on the shape of the output curve, and conversely, the possibility of identifying the course of elementary processes in the column on the basis of a given output curve. The initial purity of the sample is not essential in most

a gas chromatograph. Light-pipe-based systems are the simplest, least expensive and most reliable, but often prove to have inadequate sensitivity for the identification of minor components. Of the two deposition-based techniques, the direct deposition approach has limits of detection that rival those of benchtop GC–MS systems and has the great advantage of producing spectra that are directly comparable to KBr-disk reference spectra, of which there are over 150 000 available in digital form (i.e. suitable for computerized library searching). Thus one can forecast an increasing use of systems based on this principle in the future. It is also noteworthy that interfaces between FTIR spectrometers and both supercritical-fluid and liquid chromatographs based on the same principle have been described.

### Introduction

Nonanalytical applications of gas chromatography (GC) in the study of various phenomena in gases, solutions, and on solid surfaces are set out in **Figure 1**. They allow investigation of several phenomena in the same relatively simple apparatus, whereas other much more costly methods usually only permit the study of one such process.

The other main advantages of GC over static methods in investigating physicochemical phenomena are:

- GC is mainly used for examining very small samples at near-infinite dilution. Such concentrations can be applied directly to investigations of thermodynamic equilibrium.
- The accuracy of measurement of physicochemical phenomena by chromatography is at least as high as that of other methods, and the rate at which measurements can be made is much higher.
- Physicochemical properties may be measured over a wide range of temperature.

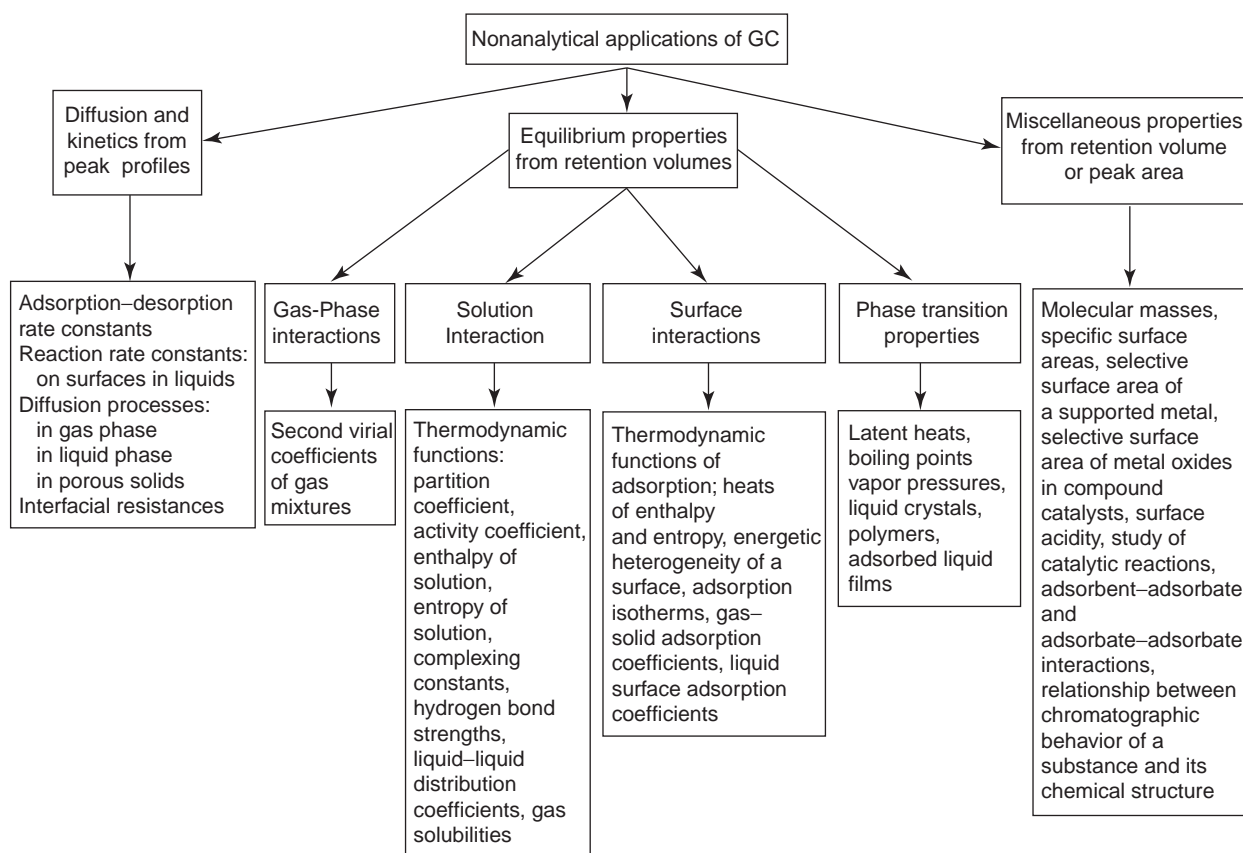

The accuracy of chromatographic results depends on whether a specific or relative retention volume,

retention time, or peak width or area is used for estimation. The accuracy is greatest for the retention time, lower for the peak width, and lowest of all for the peak area.

The precision of physicochemical measurements by GC relies on the ability of the instrument to control and measure all parameters relating to the chromatographic process. Sources of inaccuracy include the determination of stationary phase mass, column temperature and its gradients, flow rate and stability, pressure drop along the column, ‘dead space’ in the system, etc. Sophisticated computerized equipment allows precise measurement and control of all these operating parameters.

High purity of the carrier gas is essential, since even trace amounts of a contaminant that may be adsorbed will, as a result of accumulation, badly distort the results.

In analytical GC, particular emphasis is laid on the separation of the mixture into its components, which are recorded on the chromatogram as a series of peaks or steps. On the other hand, where GC is used as a physicochemical research tool, we are usually interested only in a single peak and how this alters with changes in the experimental conditions. The task is therefore to determine the effect of elementary processes taking place in the column on the shape of the output curve, and conversely, the possibility of identifying the course of elementary processes in the column on the basis of a given output curve. The initial purity of the sample is not essential in most

**Figure 1** Nonanalytical applications of GC. (Reprinted with permission from Valko *et al.* (1984) *Journal of Chromatography*, 301: 355–364; © Elsevier.)

cases and, with appropriate experimental design several physicochemical measurements can be made simultaneously on the different components in a mixture.

The appropriate sample size depends on whether the investigations are carried out in the range of 'infinite dilution' or of 'finite-concentration'. At infinite dilution, the concentrations of the components in the carrier gas may be neglected and thus the gaseous phase may be considered ideal. At finite concentration, a correction for retention calculations should be introduced, which makes them more complicated. Certain limitations of GC methods for physicochemical determinations should also be mentioned. These are mainly restricted to the study of interactions that occur on solids, in liquids, in the mobile gas phase, and at their interfaces. While measurements can be made simultaneously, it is possible that interference from other physicochemical properties of the materials may introduce inaccuracy. Another important limitation is the volatility of the stationary phase in gas-liquid chromatography.

It is impossible in this brief article to describe all the nonanalytical applications of GC presented in

**Figure 1.** They have been described in full detail in numerous monographs. Thus, the use of GC in determining some selected representative properties and parameters of particular importance in this wide field of chromatographic applications is discussed.

## Surface Characteristics

### Adsorption Isotherm

The adsorption isotherm (a plot of the concentration distribution of the solute in the mobile gas and stationary solid phases at a given temperature) is the foundation upon which the surface characteristics of adsorbents are defined. From this one can determine the specific surface area, capillary distribution (from the desorption curve), porosity, and other properties of a solid. Using adsorbates with diverse physical and chemical characteristics, it is possible to define the type of adsorbate-adsorbent interactions involved and the nature of adsorption in the system being examined.

Retention of the solute is determined by the overall equilibrium distribution between the stationary and

mobile phases. The linear isotherm is reflected in the distribution constant remaining unchanged. It may be obtained over a limited concentration range and in the absence of selective interactions between adsorbate and adsorbent. The result is a Gaussian distribution of the solute in the column eluate. If such interactions take place or if higher concentrations are employed, the sorption isotherm becomes curved, leading to an asymmetric, broadened peak shape (Figure 2). There are many methods of determining adsorption isotherms. They have been elaborated both for the case of ideal GC (elution at infinite dilution) and nonlinear nonideal GC (finite concentration), taking into consideration sorption effects, pressure gradients, gas imperfections, and other factors. Regardless of which chromatographic technique is used to determine the adsorption isotherm, the problem is to find the amount of adsorbed solute and its corresponding equilibrium concentration (pressure) in the mobile phase for each point of the isotherm. The desired data may be obtained either from a series

of adsorbate samples of varying size injected into the column (the peak maxima method) or from a single chromatogram (elution by characteristic point) and frontal analysis by characteristic point methods.

### Heat and Other Thermodynamic Functions of Adsorption

The use of temperature as a variable yields information on the thermodynamics of the adsorption-desorption process. A thermodynamic parameter of great importance measurable by GC techniques is the heat of adsorption. It provides a quantitative measure of the interactions occurring between the adsorbate and the adsorbent. The solute heat of adsorption at zero surface coverage ( $\Delta H^0$ ) is related to the retention data via

$$\ln V_g^0 = \frac{\Delta H^0}{RT} + C \quad [1]$$

where  $V_g^0$  is the solute-specific retention volume corrected to 0°C,  $R$  is the gas constant, and  $T$  is the column temperature. Plots of  $\ln V_g^0$  versus  $1/T$  yield  $\Delta H^0$  from the slope. At finite solute surface concentration (nonlinear isotherms), an accurate calculation of retention volumes from peak maxima is difficult. For such a case, therefore, initially the adsorption isotherms are estimated at various temperatures. From these, the adsorption isosters can be found, whose slope gives the isosteric heat of adsorption ( $\Delta H_{st}^0$ ):

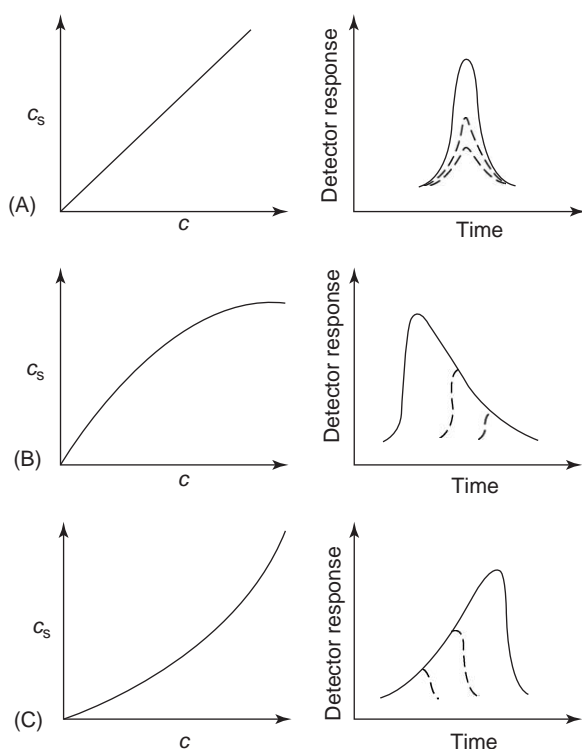

$$\ln p = \frac{\Delta H_{st}^0}{RT} + C \quad [2]$$

where  $p$  is the solute partial pressure.

The heat determined in this way depends on the coverage ( $a$ ); thus, the coverage dependence of  $\Delta H_{st}^0$  can be examined by calculating it for different values of  $a$ . Such dependence gives valuable information about features of surface interactions, the magnitude of the direct interaction of adsorbates, and the surface heterogeneity. Other thermodynamic functions of adsorption may be calculated from the temperature and coverage dependence of  $\Delta H_{st}^0(a, T)$ . The equation relating the standard free energy of adsorption  $\Delta G^0(a, T)$  to  $\Delta H^0(a, T)$  is

$$\Delta G(a, T) = \Delta G^0(a, T_0) \frac{T}{T_0} - T \int_{T_0}^T \frac{\Delta H^0(a, T)}{T^2} dT \quad [3]$$

where  $T_0$  is the temperature for which the standard free energy is defined.

**Figure 2** Shapes of adsorption isotherms and their corresponding elution peaks: (A) linear isotherm, symmetrical peak with position of peak maximum constant; (B) convex isotherm, distorted peak, tailing line spread, position of peak maximum dependent on sample size; (C) concave isotherm, distorted peak, leading profile spread, position of peak maximum dependent on sample size. (Reproduced with permission from Paryjczak T (1986) *Gas Chromatography in Adsorption and Catalysis*, p. 31. Warsaw: PWN-Polish Scientific Publishers. Chichester: Ellis Horwood.)

Having determined  $\Delta H^0(a, T)$  and  $\Delta G^0(a, T)$ , the entropy of adsorption can be calculated directly:

$$\Delta S^0(a, T) = \frac{\Delta H^0(a, T) - \Delta G^0(a, T)}{T} \quad [4]$$

### Specific Surface Area of Solids

Of all existing GC techniques for determining the specific area of a solid, the heat desorption method is the one most often used. This method was developed by Nelson and Eggertsen and modified by a number of workers. In principle, the heat desorption method is based on the traditional Brunauer, Emmett, Teller (BET) technique in which the quantity of adsorbed gas (usually nitrogen) at a temperature near its boiling point is determined. By determining the adsorption at various pressures, it is possible, using the BET equation, to calculate the amount of adsorbate required for the formation of a monolayer.

In the classic example of this method, the principle of measurement is based on the adsorption of nitrogen from a stream of nitrogen–helium or nitrogen–hydrogen mixture of a given composition at the temperature of liquid nitrogen. The sample comes to equilibrium at this temperature, indicated by a settling of the detector response. Removal of the liquid nitrogen bath results in desorption of the previously adsorbed nitrogen (Figure 3).

The quantity of adsorbed nitrogen at an appropriate relative pressure is calculated from the desorption peak since this is more symmetrical. Each experiment performed for a given concentration of adsorbate in the mixture gives one point of the adsorption isotherm.

**Figure 3** Schematic detector response in the heat desorption method: (A) adsorption peak; (B) desorption peak. (Reproduced with permission from Paryjczak T (1986) *Gas Chromatography in Adsorption and Catalysis*, p. 130. Warsaw: PWN-Polish Scientific Publishers. Chichester: Ellis Horwood.)

Easy and rapid estimation of the specific surface area of a solid is achieved using a comparative method, in which one uses the proportional relationship between the peak area and the specific surface area of the adsorbent. In this case the specific surface area of a similar standard species must be known.

The heat desorption method is widely used because of its simplicity in measurement and its great sensitivity, which means that specific surface areas can be determined over a broad range, from  $0\text{--}07\text{ m}^2\text{ g}^{-1}$  up to  $1000\text{ m}^2\text{ g}^{-1}$ .

Serpinet *et al.* have developed a GC method independent of the BET adsorption model for determining the specific areas of solids with hydroxyl groups on their surface (e.g., silica, alumina, diatomite).

### Solution Thermodynamics

According to chromatographic theory, the solute net (adjusted) retention volume  $V'_R$  is related to the solute distribution constant (partition coefficient)  $K$  by the equation

$$V'_R = KV_L \quad [5]$$

where  $V_L$  is the stationary phase volume. This relationship is strictly true when contributions from interfacial adsorption are negligible. Adsorption at the gas–liquid interface for solutes of low solubility in the stationary phase and at the liquid–solid interface for compounds with a strong affinity for the support are significant sources of error for the determination of partition coefficients under some experimental conditions. Equation [5] is appropriate when the experimental partition coefficient is independent of changes in the stationary phase volume, providing a simple test for the reliability of eqn [5]. In addition, by the purposeful variation of the stationary phase volume and extrapolation of experimental  $V'_R$  values to an infinite stationary phase volume, the partition coefficient can be estimated for conditions where interfacial adsorption contributes to the retention mechanism:

$$K = \frac{\gamma_S}{\gamma_M} \frac{C_S}{C_M} = \frac{a_S}{a_M} \quad [6]$$

where  $a$ ,  $\gamma$ , and  $C$  are the solute activity, activity coefficients, and concentrations in the stationary (S) and mobile (M) phases, respectively.

In ideal conditions, the solute in the gas phase at temperature  $T$  and pressure  $101.325\text{ kPa}$  ideally transfers to solution in the liquid phase at temperature  $T$ , unit molar concentration, and molecular interactions characteristic of an infinitely dilute solution; thus, one

can obtain a set of equations directly relating the thermodynamic functions of distribution equilibrium to the specific retention volume, corrected to 0°C ( $V_g^0$ ):

$$K = \frac{MV_g^0}{273R} \quad [7]$$

$$\Delta G_T^0 = RT \ln \frac{MV_g^0}{273R} \quad [8]$$

$$\Delta H_T^0 = RT^2 \frac{d \ln V_g}{dT} \quad [9]$$

$$\Delta S_T^0 = \frac{\Delta H_T^0 - \Delta G_T^0}{T} \quad [10]$$

where  $\Delta G_T^0$ ,  $\Delta H_T^0$ , and  $\Delta S_T^0$  are the standard partial molar Gibbs free energy, enthalpy (heat), and entropy, respectively;  $M$  is the stationary phase molecular mass.

Another pivotal thermodynamic parameter that accounts for deviations from ideal Raoult's law is the activity coefficient at infinite dilution  $\gamma^\infty$ :

$$\gamma^\infty = \frac{273R}{V_g^0 p^0 M} \quad [11]$$

where  $p^0$  is the vapor pressure of the pure solute.

The difference between the thermodynamic properties of solution, based on  $K$ , and the analogous properties of concentration from the 101–325 kPa ideal gas state may be evaluated directly from the solute activity coefficient and can be identified with the excess thermodynamic properties of solution:

$$\Delta G_E^0 = RT \ln \gamma^\infty \quad [12]$$

$$\Delta H_E^0 = -RT^2 \frac{d \ln \gamma^\infty}{dT} \quad [13]$$

$$\Delta S_E^0 = \frac{\Delta H_E^0 - \Delta G_E^0}{T} \quad [14]$$

The assumption of ideal gas-phase behavior is an approximation. For greater accuracy, fugacity and virial corrections should be applied. The corrections are small when helium, hydrogen, or nitrogen are used as mobile phases at low column pressures but may become appreciable at higher pressures and when other carrier gases are used.

In the studies interfacial adsorption should be taken into consideration as in most cases this results in the largest measurements error in partition and activity coefficients, particularly for solutes of different polarity to the stationary phase.

## Quantitative Structure–Retention Relationships

Quantitative structure–retention relationships (QSRR) are helpful in elucidation retention mechanisms, for predicting retention indices and estimating some physicochemical properties. Gas chromatographic retention is a phenomenon that is mainly dependent on molecule–stationary phase interactions. Thus, each molecule, at least in theory, will exhibit unique retention characteristics based on its chemical, structural, and electronic properties.

Numerous structural descriptors – numerical representations of molecular structure – can be used to develop statistical correlations between a compound's structure and its corresponding retention index ( $I$ ) (Kovats retention indices are the most frequently used parameters in this connection). Predictive models can be generated through multiple linear regression analysis of calculated descriptors, which are divided into four general categories: topological, geometric, physical, and electronic.

A general advantage of QSRR is that the equations derived allow the prediction of retention indices for compounds structurally similar to those used to develop the model but not represented in the initial data set. An essential condition for derivation of significant quantitative relationships between retention data and molecular structure descriptors is the precision and reliability of the chromatographic data used. Although there are several potential sources of errors in routinely determined GC retention indices, the correlations obtained are often very promising and meaningful.

Precise control of the chromatographic conditions by means of computers in modern instruments and further development of computing methods of calculation and subsequent analysis of descriptors should produce significant improvements of QSRR derived from GC, which will be especially useful for characterization of intermolecular interactions.

Abraham *et al.* presented the possibility of using GC data to correlate biological phenomena involving gaseous solutes. GC data on a given stationary phase might be suitable for the modeling of a biological process that involves the transfer of a solute from the gas phase to a biological phase.

## Catalysis

GC has been used widely to study properties of catalysts, such as diffusivity, dispersion, and selective surface area of supported catalytic systems, surface acidity, thermodynamics of adsorption, and various aspects of catalytic reactions.

In general, GC can be applied in two ways to study catalytic reactions. In the first, the catalyst is placed inside the chromatographic column. Substrates are usually injected pulsewise into the stream of carrier gas. Packed with catalyst, the column acts as both reactor and separating column. A chemical reaction taking place under the so-called chromatographic conditions differs from one occurring normally in that the intermediate and final products are generally separated from the substrates, thus preventing any reaction between them. Obviously, the kinetics of catalytic reactions taking place on a chromatographic column differs fundamentally from the kinetics of reactions occurring in flow or flow-circulation apparatus or in a microreactor. This method is particularly suitable for studying the mechanism of contact processes.

In the second method, a microreactor, in which the catalytic reaction proceeds, is placed immediately before the chromatographic column. The substrates, injected pulsewise into the carrier gas, pass into the microreactor and from there into the chromatographic column for postreaction analysis. This is a very promising technique, used to analyze such physicochemical properties of catalysts as their activity, selectivity, and catalytic reaction mechanisms. The microreactor technique provides advantages of simplicity and rapidity of measurement; high sensitivity; the capacity to operate with very small quantities of reactants and catalysts; isothermicity, since local overheating is avoided; and analysis of the initial periods of operation of a catalyst and its poisoning. Finally, the coefficients of adsorption of the reactants can be determined, and thus also the surface concentration of the reactants, which enables the real reaction rate constant to be established. However, pulse techniques do not guarantee constant conditions of the process, and data obtained using them do not define the rate of reaction, which is measured in flow and flow-circulation methods. This results from the fact that the reactant concentrations vary, as does the state of the catalytically active surface, its chemical composition, degree of oxidation or reduction, etc.

When using the pulse technique to study catalytic processes in the microreactor, it is important to select correctly the input volume of the pulse ( $V_p$ ) and the volume of the catalyst ( $V_{cat}$ ). If the ratio  $V_p/V_{cat} \gg 1$ , the results obtained with this method basically correspond to those from the traditional flow method; thus, the pulse microreactor can be regarded as a flow reactor in which the movement of the pulse takes place under ideal piston displacement conditions.

If the volumetric ratio of the pulse and catalyst is inverted, i.e., when  $V_p/V_{cat} \ll 1$ , in a number of cases the catalytic reaction will take place under

chromatographic conditions. The considerable concentration gradient of the reactants interferes with the working up of the results, but nevertheless these are very valuable in analyzing reaction mechanisms.

The surface of the catalyst during a reaction proceeding under pulse conditions is constantly renewed by the carrier gas flowing over it at the reaction temperature. Since very small amounts of the reactant are introduced into a microreactor working under chromatographic conditions, one may assume that the results refer to the properties of that section of the catalyst's surface that was not affected by the reaction mixture. On the other hand, if pulses are introduced rapidly one after another, the change in the catalyst's activity during the chemical reaction can be assessed. The catalytic activity of the first pulses is often greater than that estimated under stationary conditions by a few orders of magnitude.

The processes involved in the flow of a pulse of reactant through a layer of catalyst, such as diffusion, adsorption, and desorption, exert a significant influence on the reaction kinetics. The study of catalytic reactions under chromatographic conditions is especially suitable when the equilibrium constant of the reaction is small but the rate of reaction sufficiently fast. It is the separation of products and not the rate of reaction that then limits the extent of the process.

For irreversible reactions of first order, the rate constant  $k$  may easily be obtained from Bassett and Habgood's equation, often used in the literature:

$$kK = \frac{F_c^0}{273Rm} \ln \frac{1}{1-\alpha} \quad [15]$$

where  $k$  and  $K$  are the rate constant and Henry's constant, respectively,  $F_c^0$  is the volumetric flow rate under normal conditions,  $m$  is the mass of the catalyst,  $R$  is the gas constant, and  $\alpha$  is the degree of conversion.

Practical applications of GC methods for assessing catalytic activity and studying heterogeneous reaction are outrunning the development of the theory of nonstationary processes under pulse conditions. Although numerous models describing different types of both reversible and irreversible reactions have been elaborated, many theoretical problems are still far from solution.

## Surface Acidity

The temperature programmed desorption method originating from GC is most commonly used in determining the surface acidity of catalysts.

The catalytic activity of a large group of catalysts used in isomerization, polymerization of alkenes, cracking, hydrocracking, dehydration of alcohols, manufacturing of alkyl ethers, reforming on bifunctional catalysts, and many other processes is due to the acidity of their surfaces. The knowledge of the number and strength of acid sites and also type of acidity (Brönsted and Lewis) involved is very important as it helps to explain the mechanism of reactions occurring at the surface of these catalysts.

Mostly ammonia but also pyridine, aniline, *N*-methyl tetrahydropyrrole, diethylamine, isopropylamine, and cyclohexylamine are used as probe particles, whose desorption is the source of information on acid centers.

The basis of temperature programmed desorption (TPD) method is chemisorption of base vapor, ammonia being most often used, on the surface of an acidic catalyst at a given temperature, followed by its desorption as a result of a temperature rise. The area of the obtained desorption peak gives the total acid site density and the maximum of the peak characterizes the activation energy of desorption and may be considered as a measure of the acid strength.

Figure 4 shows TPD ammonia spectra where the h-peak is the desorption peak of ammonia that was adsorbed on the acid sites, whereas the l-peak was assigned to ammonia weakly held or physically adsorbed on the zeolite.

Niwa *et al.* derived an equation describing TPD of ammonia for zeolites including its readsorption. The equation allows for calculating acidity strength expressed as a change of desorption enthalpy  $\Delta H$ :

$$\ln T_m - \ln \frac{A_0}{F} = \frac{\Delta H}{RT_m} + \ln \frac{\beta(1 - \Theta_m)^2(\Delta H - RT_m)}{P^0 \exp(\Delta S/R)} \quad [16]$$

where  $T_m$  is the maximum peak temperature,  $A_0$  the number of acid sites,  $W$  the mass sample,  $F$  the flow rate of carrier gas,  $\Delta S$  the change of desorption entropy, and  $P^0$ ,  $R$ ,  $\beta$ ,  $\Theta$ , the pressure (standard conditions), gas constant, heat rate, degree of surface coverage at maximum peak temperature, respectively. This equation shows the dependence of  $T_m$  on the parameters of TPD.

## Other Applications

### Complexation Equilibrium

Metal ions can act as electron-pair acceptors, reacting with electron donors to form coordination compounds or complexes with either the stationary phase

**Figure 4** TPD spectra on H-mordenite ( $\text{SiO}_2/\text{Al}_2\text{O}_3 = 15.0$ ) and H-ZSM-5 ( $\text{SiO}_2/\text{Al}_2\text{O}_3 = 23.8$ ), l- and h-peaks due to low and high temperatures of desorption. (Reproduced with permission from Niwa M and Katada N (1997) Measurement of acidic property of zeolites by temperature programmed desorption of ammonia. *Catalysis Surveys from Japan* 1: 215–226.)

or the mobile phase. Such complexation imparts a high degree of selectivity to the GC system, and the chromatographic data can be used to calculate the stability constants and related parameters of the complexes.

### Polymer Studies

Physical properties of polymers have frequently been studied using the polymers as stationary phases. Interactions between solvents and polymers such as the adsorption propensity of the polymeric stationary phases or solubility in polymer films can readily be determined by GC.

Polymers can also be identified and studied by pyrolysis followed by GC analysis of the volatile breakdown products.

### Virial Coefficients

Development of the theory of virial corrections to partition coefficient data has led to the use of GC for the direct measurement of virial coefficients. In general, the method of determination of virial coefficients by GC consists of measuring the retention volumes at various carrier gas pressures and extrapolating to zero pressures.

Gas–solid virial coefficients, characterizing the interaction of the adsorbate molecule with the surface of the solid, can be used to estimate surface area and for quantitative studies of the energetic heterogeneity of a surface.

### Liquid Crystals

GC on liquid-crystalline stationary phases can be used for investigation of the physicochemical

properties of the liquid crystals, particularly the phenomena occurring in the transition zones. Using GC methods, phase diagrams of liquid crystals, the degree of ordering of the liquid-crystal molecules, and the relationship between the liquid-crystal molecular orientation and the polarity of the substrate surface can also be determined.

## Environmental Analysis

Gas chromatography (GC) is one of the most frequently used chromatographic separation techniques for the determination of the presence of organic contaminants in the environment. The popularity of GC is due to a favorable combination of very high sensitivity and resolution, wide dynamic concentration range, and high selectivity. The constant advance in the development of new and robust stationary phases and detectors has made GC a highly reliable tool for routine trace analysis. Moreover, the introduction of fused-capillary columns and the coupling of GC with mass spectrometry (MS) have enabled the most advanced analytical technique currently available for volatile solutes. GC is also a valuable reference technique for environmental analysis. The vitality of GC is also reflected in the development of new technologies such as high-speed GC (HSGC) and comprehensive two-dimensional GC (GC × GC). Such technologies greatly increase the separation capabilities of GC.

A wide range of organic environmental pollutants are highly suitable for GC analysis as they are relatively nonpolar compounds with relatively low molecular mass (<500) and are stable at the normal range of temperatures used for GC (50–350°C). Due

to the low concentration of organic pollutants present in the environmental samples, ranging from micrograms per gram to femtograms per gram, an extensive cleanup and fractionation of the analytes is needed before GC analysis. The complexity of the cleanup steps depends on the sample matrix and the concentration of the analytes. Thus, for relatively clean water samples, a simple procedure is often used, whereas for sediments or biota, complex cleanup procedures are needed. Quality assurance of the complete method including GC determination is required to obtain reliable results in environmental analysis.

## Columns

The introduction of capillary columns for GC analysis produced a breakthrough in the analysis of environmental pollutants due to their high separation efficiency. For environmental applications, fused-silica wall-coated open-tubular columns with internal diameters from 0.1 to 0.32 mm and film thickness of 0.1–0.2 µm, and lengths from 25 to 60 m are currently used. The wide range of stationary phases commercially available with different polarities and high thermal stability provides the tool required to maintain the prominent position of GC in environmental analysis. In addition, the availability of chiral stationary phases gives GC the capability to perform GC enantiomer separations. **Table 1** gives the recommended columns used in routine analysis of some selected pollutants.

properties of the liquid crystals, particularly the phenomena occurring in the transition zones. Using GC methods, phase diagrams of liquid crystals, the degree of ordering of the liquid-crystal molecules, and the relationship between the liquid-crystal molecular orientation and the polarity of the substrate surface can also be determined.

Such technologies greatly increase the separation capabilities of GC.

A wide range of organic environmental pollutants are highly suitable for GC analysis as they are relatively nonpolar compounds with relatively low molecular mass (<500) and are stable at the normal range of temperatures used for GC (50–350°C). Due

to the low concentration of organic pollutants present in the environmental samples, ranging from micrograms per gram to femtograms per gram, an extensive cleanup and fractionation of the analytes is needed before GC analysis. The complexity of the cleanup steps depends on the sample matrix and the concentration of the analytes. Thus, for relatively clean water samples, a simple procedure is often used, whereas for sediments or biota, complex cleanup procedures are needed. Quality assurance of the complete method including GC determination is required to obtain reliable results in environmental analysis.

## Columns

The introduction of capillary columns for GC analysis produced a breakthrough in the analysis of environmental pollutants due to their high separation efficiency. For environmental applications, fused-silica wall-coated open-tubular columns with internal diameters from 0.1 to 0.32 mm and film thickness of 0.1–0.2 µm, and lengths from 25 to 60 m are currently used. The wide range of stationary phases commercially available with different polarities and high thermal stability provides the tool required to maintain the prominent position of GC in environmental analysis. In addition, the availability of chiral stationary phases gives GC the capability to perform GC enantiomer separations. **Table 1** gives the recommended columns used in routine analysis of some selected pollutants.

**Table 1** Recommended capillary columns for the determination of selected pollutants

<i>Stationary phase</i>	<i>Compound</i>
Methylpolysiloxane	Polycyclic aromatic hydrocarbons, disinfection by-products, organochlorine pesticides, chlorinated paraffins
5% Phenyl methylpolysiloxane	Polycyclic aromatic hydrocarbons, disinfection by-products, polychlorinated biphenyls, polychlorinated dibenzo- <i>p</i> -dioxins and dibenzofurans, organochlorine pesticides, polybrominated biphenyls, polybrominated diphenyl ethers, chlorinated paraffins, methyl- <i>tert</i> -butyl-ether
14% Cyanopropylphenyl methylpolysiloxane	Disinfection by-products (derivatized aldehydes), polychlorinated biphenyls, polychlorinated dibenzo- <i>p</i> -dioxins and dibenzofurans, pesticides, polybrominated diphenyl ethers
50% Phenyl methylpolysiloxane	Polychlorinated biphenyls, pesticides
Specific columns	Polychlorinated biphenyls (DB-XLB, HT-8); polychlorinated dibenzo- <i>p</i> -dioxins and dibenzofurans (DB-Dioxin)

Recently, HSGC has been applied to the analysis of some environmental pollutants such as pesticides, polychlorinated biphenyls (PCBs), and polycyclic aromatic hydrocarbons (PAHs). Using this technique, fast separations have been obtained using short capillary columns (<10 m) with internal diameters of 50  $\mu$ m. An important reduction in analysis time can be achieved so that separations by conventional capillary GC that are obtained in 20 min take no longer than 20 s using this technique.

An important improvement in the separation capacity of GC can be obtained using comprehensive GC  $\times$  GC. This involves the use of two capillary columns with different separation mechanisms by which the second column separates unresolved compounds that elute from the first. The instrument design uses a modulator interface that couples the two columns. The first column is generally a conventional nonpolar GC column, the second one being a short polar column that allows very fast separation. This technique has proved to be a promising tool for the unambiguous separation of several contaminants such as PAHs, PCBs, polychlorinated dibenzo-*p*-dioxins and dibenzofurans (PCDD/Fs), and pesticides in environmental samples.

### Sample Introduction

The low concentration levels of the compounds in environmental samples impose specific requirements in terms of sample injection for GC analysis. In addition to the common injection techniques of capillary GC (split, splitless, on-column, and programmed temperature vaporized (PTV) injection), some other sample introduction methods coupled to GC such as solid-phase microextraction (SPME), headspace, etc., have favored the versatility of GC and reduced the time required for sample preparation. These techniques have an advantage over the conventional injection methods, which is that a preconcentration step prior to GC

analysis can be performed; therefore, an enhancement on the sensitivity of the GC method is obtainable.

Splitless and on-column are the most useful injection techniques, although in recent years the use of the PTV injector has increased as a result of its capacity to reduce discrimination effects in the injector of analytes with high boiling points. Moreover, PTV and on-column injectors allow direct GC analysis of water samples using large-volume injection. PTV and on-column injectors have been successfully applied to pesticide residue analysis in water. In ambient air analysis, the sampling and preconcentration procedures most widely used are sorbent sampling and the cryogenic method. Different solid sorbents have been used for the analysis of volatile organic compounds (VOCs) and semi-VOCs, the desorption of which is performed thermally or by means of an organic solvent. Other techniques often used for the analysis of VOCs, such as headspace, purge and trap, and closed-loop stripping analysis can be easily combined off- or online with the GC system. Solid-phase extraction (SPE) methods coupled to GC have also been used for the analysis of environmental contaminants, mainly for pesticides. SPE technique allows an important preconcentration of the analytes and can be coupled directly to the GC injector if it is combined with large-volume injection techniques. SPME is an inexpensive and easily automated technique based on sorptive extraction that has shown itself to be a good alternative to liquid extraction. This technique, combined with GC, has been applied to the analysis of a great number of organic contaminants, e.g., BTEX (benzene, toluene, ethylbenzene, and xylenes), polar solvents, PAHs, pesticides, PCBs, and disinfection by-products (DBPs) in different environmental samples such as water and soils. Another solventless sample preparation technique recently developed is stir bar sorptive extraction which, followed by thermal desorption, has been proposed for the analysis of pollutants in water.

## Detection

One important feature of GC is the availability of selective and sensitive detectors. The flame ionization detector (FID) is the most popular system for environmental analysis because it responds to nearly all organic compounds. However, FID has a detection limit in the low nanogram range, reducing its applicability to the determination of major contaminants. Selective detectors such as the electron-capture detector (ECD), thermionic ionization detector (TID), flame-photometric detector (FPD), and atomic emission detector (AED) are currently used for the determination of a specific group of contaminants in environmental samples. ECD has a high sensitivity (picogram to femtogram range) and selectivity for detecting halogen-containing compounds. This detector has been widely applied for the analysis of PCBs, halogenated pesticides, PCNs, and brominated organic compounds. In comparison with the FID system, nitrogen and phosphorus detectors have the ability to enhance the ionization of N and P compounds, allowing low detection limits and good selectivity over (interfering) carbon compounds. FPD and the more recently developed pulsed flame photometric detector have an important field of applications in the detection of phosphorus and sulfur organic compounds. The element-selective detector for GC, the AED, has a high selectivity and has led to numerous applications, mainly for pesticide analysis.

GC coupled to mass spectrometry (GC-MS) has proved to be an advantageous and powerful technique for the analysis of a wide range of environmental contaminants, mainly because of the high sensitivity, selectivity, and versatility. In fact, selective detectors have progressively been replaced by GC-MS. The very high number of applications is the result of the efficiency of separation by GC and the good qualitative information and sensitivity provided by mass spectrometry. The MS fragmentation pattern can often provide unambiguous component identification by comparison with library spectra in electron ionization (EI). In addition, the use of chemical ionization (CI) provides better selectivity and sensitivity than EI and, in some cases, this ionization mode allows to achieve limits of detection similar to those obtained with selective detectors. Several analyzers are currently used in GC-MS. The most popular is the single quadrupole analyzer, but the ion-trap analyzer has achieved a prominent position in environmental applications. The reason for this lies in the enhancement selectivity obtainable in ion-trap tandem MS (MS/MS) mode, which carries with it the additional advantage of confirmation capabilities using the full-scan spectra of product ions.

## Applications

### Polycyclic Aromatic Hydrocarbons

PAHs represent an important class of environmental pollutants that have gained special attention because some of them are strong mutagens and carcinogens. PAHs are natural constituents of crude oil and many other petrochemical products, but they can also be formed by incomplete combustion of fossil fuels and other organic matter. Natural sources of PAH emission such as forest fires and volcanic eruptions have always existed but there has been an increase in the loading of the environment by anthropogenic sources that include incomplete combustion or the spillage of fossil fuel. On the basis of frequency of occurrence in the environment and their proved mutagenicity and carcinogenicity, 16 PAHs were selected in 1997 by the US Environmental Protection Agency (USEPA) as priority pollutants. Identification of these compounds in environmental samples is important in order to determine their specific emission sources, a step that would help the authorities to establish strategies to reduce PAH emissions into the environment. Pyrolytically produced PAHs from incomplete combustion of organic fuels such as oil, wood, or petrol can be distinguished from those of direct fossil fuel origin by the strong dominance of the unsubstituted parent PAH.

Capillary GC, first used to separate PAHs in 1964, is now one of the standard methods for the determination of these compounds in environmental matrices. Speed of analysis, high power of resolution, and low detection limits are the advantages of GC procedures. Since the PAHs most likely to be found in the environment are those that are volatile and semivolatile (up to 24 carbon atoms), they are analyzable by GC. In general, nonpolar stationary phases such as methylpolysiloxane or 5% phenyl methylpolysiloxane are the most adequate for the separation of these compounds in routine applications. Cold on-column injection is preferred as it improves both the resolution obtained for the first-eluting compounds and discrimination against high molecular weight compounds, which is difficult to avoid completely using splitless injection. The FID is normally adequate for sensitive detection, but coupling GC with MS affords greater selectivity through the application of selected ion monitoring. EI has been successfully applied to the analysis of these compounds but PAH isomers are almost always indistinguishable. To differentiate between PAH isomers, positive CI with methane, a mixture of methane/argon, or dimethyl ether as reagent gas is used. Nowadays, GC continues to be a popular technique for the analysis of PAHs because of its proven capabilities. Moreover, the technique is well established

and GC instrumentation is a common feature in routine analytical laboratories.

### Disinfection By-Products

Disinfection of drinking water is one of the major public health triumphs of the twentieth century. Today, most of the pathogenic microorganisms in water are killed when oxidizing chemicals such as chlorine, ozone, chlorine dioxide, and chloramines are added to the water in municipal treatment plants. Nevertheless, chemical DBPs are produced when disinfectants react with natural organic matter present in water. Trihalomethanes (THMs) are the main DBPs formed when chlorine is used but other compounds such as haloacetic acids (HAAs), haloacetonitriles (HANs), and haloketones (HKs) are also found in drinking water. The presence of DBPs in drinking water is a health hazard and may also cause unpleasant taste and odor. For these reasons, the occurrence of DBPs in drinking water has been evaluated and regulatory legislation has been established.

Purge-and-trap, liquid-liquid extraction, SPE, and headspace extraction are the most common preconcentration techniques used as a first step for control of DBPs in drinking water. Moreover, in the last few years SPME has been proposed for the analysis of several DBPs, with very good results. Table 2 provides a summary of the USEPA methods proposed for the analysis of DBPs in drinking water. For quantification of the halogenated high-priority compounds (THMs, HAAs, HANs, and HKs), GC is the technique of choice. Several detection systems have been used but ECD is the most popular due to its low cost and the high selectivity provided by this detector for halogenated compounds. Nevertheless, single quadrupole GC-MS instruments in SIM mode and ion-trap analyzers in full scan or MS/MS are also frequently used. Some DBPs are not amenable to GC analysis and have to be derivatized. For instance, HAAs are mainly deprotonated, so they cannot be extracted from water and injected into a GC column. Methylation with diazomethane or acidic methanol

is the approach proposed for the analysis of these compounds (Table 2). Aldehydes, which are mainly formed when ozone is used as disinfection reagent, are polar compounds, making it difficult to separate DBPs from the water matrix. Therefore, derivatizing agents that convert the polar groups into less polar ones are used. For instance, these compounds are analyzed by GC after oximation with pentafluorobenzylhydroxylamine (PFBHA). In general, capillary columns with stationary phases such as the nonpolar methylpolysiloxane (DB-1), the slightly polar ones with 5% of phenyl groups such as DB-5 and the DB-624 specially designed for the analysis of volatile priority pollutants, are employed to control DBPs in water. These columns are used for THM, nitriles, ketones, and methylated HAAs. The more polar stationary phase, 14% cyanopropylphenyl methylpolysiloxane, such as DB-1701 and CPSil19 CB, is currently used for analysis of the PFBHA derivatized aldehydes. Figure 1 shows as an example of the chromatogram of a water sample spiked with aldehydes.

### Polychlorinated Biphenyls

PCBs have been used extensively in electronic equipment as dielectric in capacitors and transformers, hydraulic fluids, and as plasticizers. These compounds have been withdrawn from use or have remained in very restricted use since 1977. Nevertheless, the widespread use and persistence of PCBs in the environment are the cause of their ubiquitous presence around the world. Recently, these compounds have received special attention due to their properties as endocrine disruptors and environmental estrogens. PCBs are found as complex congener mixtures, consisting of a large number of major and minor components. From the total number of possible congeners (209 compounds), ~100 can be identified in environmental samples, but analysis of PCBs is at present almost exclusively carried out on a congener-specific basis. Seven selected individual congeners (PCBs 28, 52, 101, 118, 138, 153, and 180), which are considered as indicators of

**Table 2** EPA methods for the analysis of disinfection by-products (DBPs) in drinking water

Compounds	EPA method	Procedure
Trihalomethanes	502.2	Purge and trap, GC-photoionization-electrolytic conductivity detection
Trihalomethanes	524.2	Purge and trap, GC-MS
Trihalomethanes	551.1	Liquid-liquid extraction, GC-ECD
Haloacetic acids	552	Liquid-liquid extraction, diazomethane methylation, GC-ECD
Haloacetic acids	552.1	Anion exchange resin, acidic methanol methylation, GC-ECD
Haloacetic acids	552.2	Liquid-liquid extraction, acidic methanol methylation, GC-ECD
Haloacetic acids	552.3	Liquid-liquid microextraction, acidic methanol methylation, GC-ECD
Aldehydes, ketones	556	Oximation, liquid-liquid extraction, GC-ECD

PCB contamination, are currently analyzed by capillary GC. In addition to these compounds, other PCB congeners such as PCBs 105, 128, 149, 156, and 170 are also monitored due to their toxicity and their large contribution to total PCB contamination. Complete separation of all congeners is impossible on a single capillary column, and the use of at least two columns with different stationary phases is recommended. Thus, nonpolar stationary phases such as 5% phenyl methylpolysiloxane (for instance, DB-5 or CPSil 8CB) and medium polar columns such as 14% cyanopropylphenyl methylpolysiloxane (for instance, DB-1701) or 50% phenyl methylpolysiloxane (for instance, DB-17), or a polar stationary phase such as HP-FFAP (nitroterephthalic acid modified-polyethylene glycol) are currently used. Specially developed stationary phases for PCB analysis such as DB-XLB or HT-8 (carborane backbone phase) show a low number of congener co-elutions that in some cases can be resolved by MA. By using a good selection of columns, an unequivocal separation and identification of the individual congeners can be obtained.

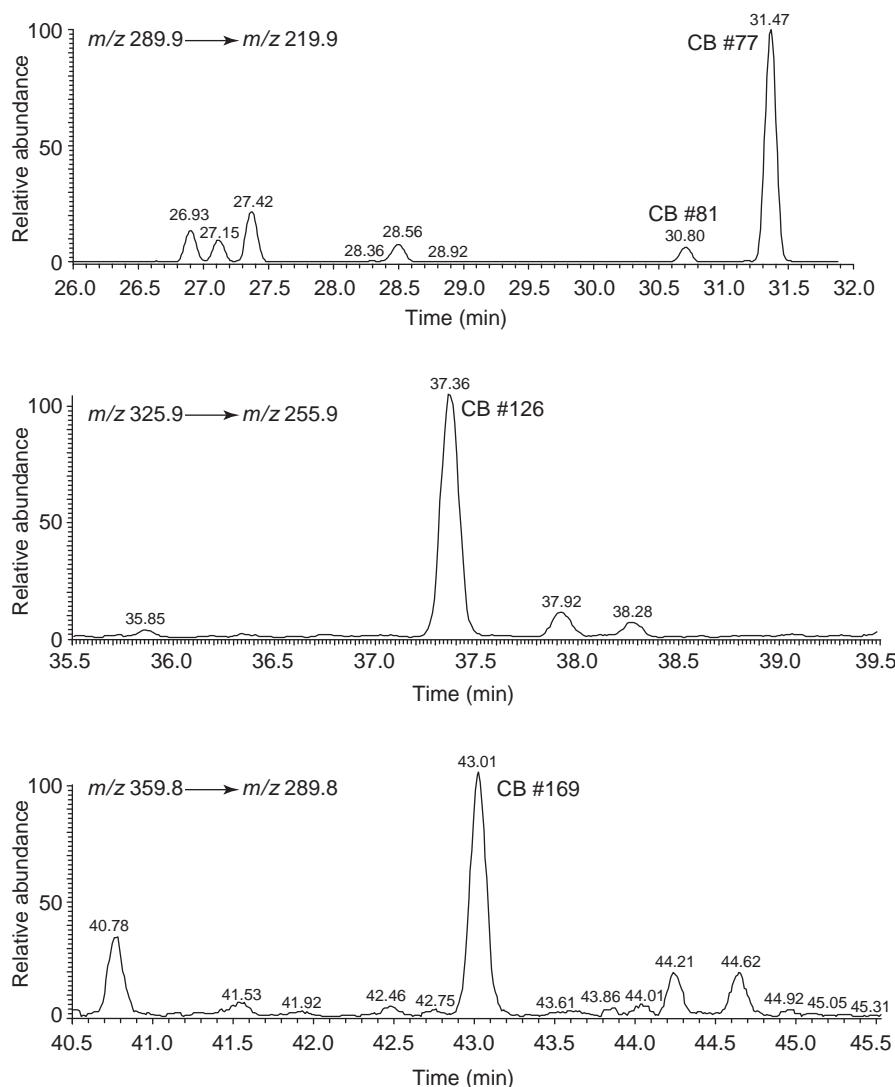

Over the course of the last few years, increasing attention has been focused on the study of non-*ortho* substituted (PCBs 77, 81, 126, and 169) and mono-*ortho* substituted PCBs (PCBs 105, 114, 118, 123, 156, 157, 167, and 189). These are also called dioxin-like PCBs. These substances show the same type of toxicity as polychlorinated dibenzo-*p*-dioxins and dibenzofurans. The main problem in the analysis of the non-*ortho* PCBs is their extremely low concentration compared with other PCBs. In most environmental samples the concentration difference between these compounds and the major PCBs ranges between 100 and 3000 times. Therefore, a separation of these compounds from other PCBs before GC analysis is required.

GC coupled with low-resolution MS (LRMS) provides the required sensitivity and selectivity for the determination of PCBs. Nevertheless, the use of high-resolution mass spectrometry (HRMS) at a resolution between 6000 and 10 000 in EI mode allows complete removal of the contribution of matrix interfering compounds, achieving low limits of detection (20–100 fg). Therefore, this is the technique of

choice when the dioxin-like PCBs are analyzed in environmental samples. The negative chemical ionization (NCI) mode can be used as an alternative to the EI mode to achieve lower limits of detection (6–100 times), but problems with the reproducibility and instrument-to-instrument variability makes its routine use difficult. Recently, however, GC ion-trap MS working in tandem mode (GC-ITMS/MS) has been successfully applied to the analysis of these compounds in environmental samples. This technique provides very high selectivity, although limits of detection are slightly higher than HRMS (60–300 fg). As an example, the GC-ITMS/MS chromatograms corresponding to the non-*ortho*-PCBs from a fish sample (chub) are given in Figure 2.

### Polychlorinated Dibenzo-*p*-Dioxins and Dibenzofurans

Polychlorinated dibenzo-*p*-dioxins (PCDDs) and dibenzofurans (PCDFs) are the most hazardous environmental pollutants that have received prolonged attention by the scientific community and by environmental regulation. These compounds are not commercially produced but can be formed during combustion processes, such as municipal waste incineration, in which halogenated compounds are exposed to very high temperatures. Other primary sources of formation of these compounds are related to various chemical processes that result in contaminated products and waste. Although there are theoretically 75 PCDFs and 135 PCDDs, only 17 of them

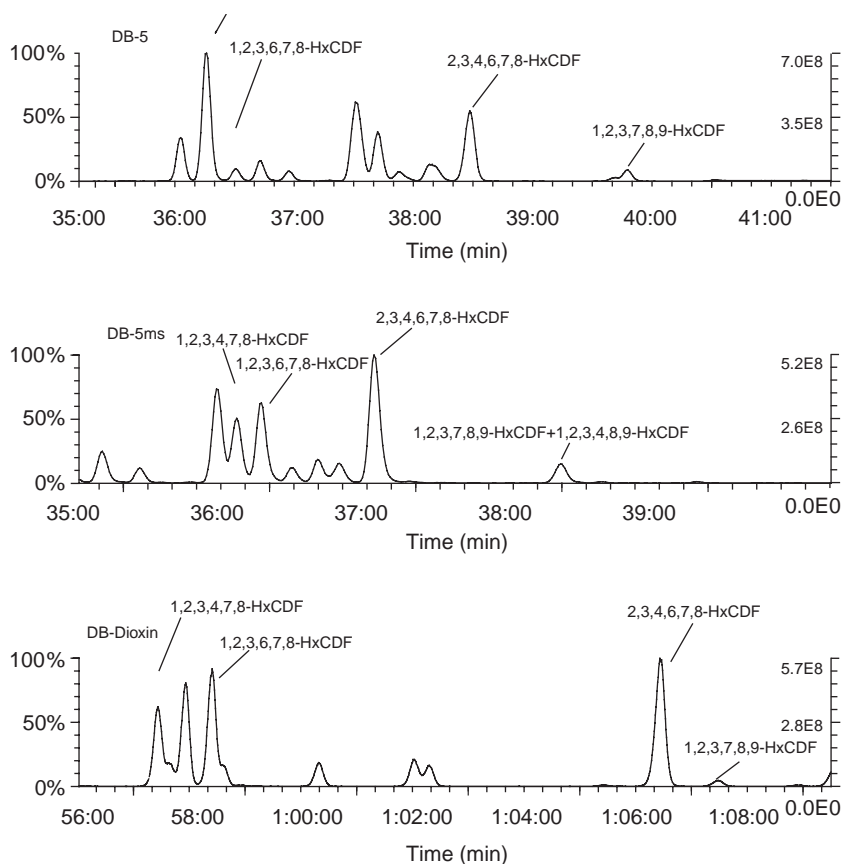

**Figure 2** GC-ion trap MS/MS chromatograms of the non-*ortho*-PCBs (PCBs 77, 81, 126, and 169) in a fish sample. Experimental conditions: GC column: DB-5 (J&W Scientific) 60 m  $\times$  0.25 mm ID, 0.25  $\mu$ m film thickness. MS analyzer: ion-trap MS, working in full-scan product mode. (Reproduced with permission from Malavia J, Santos FJ, and Galceran MT (2002) Ion trap MS/MS as alternative to HRMS for the analysis of non-*ortho*-PCBs in biota samples. *Organohalogen Compounds* 55: 103–106.)

(seven 2,3,7,8-substituted PCDDs and 10 PCDFs) are regularly analyzed and found in environmental samples. Of these, 12 are considered to be more toxic than the others, especially 2,3,7,8-tetrachloro-dibenzodioxin, which has the highest toxicity. Owing to the very lipophilic character of PCDD/Fs, they accumulate in biota and are considered a potential health risk for humans as well as for animals.

GC with fused-silica capillary columns with different stationary phases such as 5% phenyl methylpolysiloxane (DB-5, DB-5ms), 44% methyl-28% phenyl-20% cyanopropylpolysiloxane (DB-Dioxin) or cyanopropylpolysiloxane (SP-2330 or CPSil-88) are currently used, although problems related to the co-elution of some congeners have been described. Column lengths of ~50–60 m have to be used. Generally, a complete separation of the toxic PCDD/Fs from other congeners cannot be accomplished using only a single column. For instance, nonpolar stationary phases enable the separation between homolog groups

and between 2,3,7,8-chloro-substituted congeners, but some co-elutions between toxic and less toxic PCDD/F congeners are produced. An enhancement in the resolution can be obtained using more polar stationary phases such as CPSil-88 and SP2330, but the separation of 2,3,7,8-TCDD, 1,2,3,7,8-PeCDF, and 1,2,3,4,7,8-HxCDF remains incomplete. In the same way, the polar stationary phase DB-Dioxin, which was especially developed for the analysis dioxins and furans, allows the successful separation of all 2,3,7,8-chloro-substituted dioxins and furans, but 1,2,3,7,8-PeCDF, 2,3,4,7,8-PeCDF, and 1,2,3,6,7,8-HxCDF co-elute with other less toxic furans. **Figure 3** shows an example of the separation obtained of the 2,3,7,8-chloro-substituted HxCDFs from other less toxic congeners using three different capillary columns, DB-5, DB-5ms, and DB-Dioxin. The choice of the columns depends on the sample analyzed, but the use of at least two columns of different polarity is recommended for the complete isomer separation.

**Figure 3** GC-HRMS selected ion monitoring of hexachlorodibenzo-*p*-dioxins ( $m/z$  373.8207) of a municipal waste incineration emission on DB-5, DB-5ms, and DB-Dioxin GC columns. Experimental conditions: GC columns: DB-5, DB-5ms, and DB-Dioxin (J&W Scientific) 60 m  $\times$  0.25 mm ID, 0.25  $\mu$ m film thickness. MS conditions: EI + at a resolution of 10 000 (10% valley definition). SIM mode. (Reprinted with permission from Abad E, Caixach J, and Rivera J (1997) Application of DB-5 ms gas chromatography column for the complete assignment of 2,3,7,8-substituted polychlorodibenzo-*p*-dioxins and polychlorodibenzofurans in samples from municipal waste incinerator emissions. *Journal of Chromatography A* 786: 125–134.)

The analysis of PCDD/Fs is difficult due to the low concentration levels (part per trillion) found in the environmental samples. GC–HRMS is the only technique capable of providing the required selectivity and sensitivity for the analysis of these compounds, and it is considered the reference technique for such analysis. Working in selected ion monitoring (SIM) mode at a mass resolution of 10 000, the presence of matrix components in the extracts does not interfere and detection at a high level of mass accuracy can be obtained. Quantification is generally performed by using stable isotope-labeled  $^{13}\text{C}_{12}$  analogs of the target compounds as internal standards (isotope dilution method). EI is the most popular ionization technique, although NCI, with methane as reagent gas, can be used for improving molecular mass determination and increasing sensitivity. Limits of detection for GC–EI–HRMS down to 10–200 fg have been obtained with the newest generation of HRMS systems. In recent years, ion-trap tandem mass spectrometry has been proposed as an alternative technique to HRMS for the analysis of these compounds. However, further studies related to the sensitivity and the selectivity of this technique must be performed in order to assure the quality of the results.

### Pesticides

The extensive use of pesticides to improve agricultural productivity played an important role in the twentieth century. These compounds have been applied for years to control the effect of pests and to increase food production. They were especially widely used after World War II. Nevertheless, this widespread use and the additional environmental pollution due to industrial emissions during their production have resulted in the occurrence of residues of these chemicals and their metabolites in the environment and the food chain. Since some of these compounds are important carcinogens and mutagens, regulation and environmental monitoring programs have been adopted in order to determine the risks to human health. At present, over 500 compounds are registered worldwide as pesticides or metabolites of pesticides. From these, organochlorine pesticides (OCPs) have been the most intensely used for agricultural purposes due to their insecticidal properties. OCPs such as those of the DDT group, HCH and its isomers, and cyclodienes are often detected in environmental samples, and they are ubiquitous across the globe, even in remote Polar Regions. Although most OCPs have been banned since the 1970s, they and their metabolites are still frequently found in different environmental samples due to their high persistence and lipophilicity, and they remain an

important source of contamination throughout the food chain. Organophosphorus (OPPs) and organonitrogen pesticides (ONPs) have been used to replace OCPs in many agricultural applications due to their lower toxicity and low residence time in the environment.

Capillary GC is the technique of widest application in pesticide analysis. Nowadays, more than 60% of the total pesticide and/or metabolites registered are amenable to GC. Only polar or semipolar pesticides are analyzed by using other techniques such as liquid chromatography. The selection of the GC stationary phase depends on the nature of the pesticides to be separated. For instance, for organochlorine and pyrethroid pesticides, nonpolar stationary phases such as methylpolysiloxane or 5% phenyl methylpolysiloxane are currently used. On the other hand, for the separation of more polar pesticides such as organophosphorus compounds, semipolar stationary phases such as 14% cyanopropylphenyl methylpolysiloxane or 50% phenyl methylpolysiloxane are often preferred, while polar stationary phases, e.g., DB-wax, are suitable for more polar compounds such as methamidofos. Splitless injection is currently used for GC analysis of pesticides due to its robustness, but on-column and PTV injectors have also been used. Moreover, direct injection of large volumes combined with PTV is an interesting approach for the analysis of pesticides in water samples with an important reduction of the detection limits. Due to the different characteristics of the pesticides, selective detectors based on the measure of some specific properties are currently used in their quantification so as to achieve enough selectivity and sensitivity. For instance, ECD is used for the analysis of halogenated pesticides, TID for triazines and organophosphorous pesticides, and FPD for organotin and organosulfur compounds. Nevertheless, the use of these selective detectors is being progressively replaced by GC–MS for pesticide residue analysis, mainly due to the proved high sensitivity of CI and the high selectivity of MS/MS. Moreover, ion-trap MS working in MS/MS mode has shown itself to be a powerful technique for pesticide residue analysis at low concentration levels.

### Emerging Contaminants

A new and important field of research in environment analysis is the study of the so-called emerging contaminants. These compounds are mainly unregulated pollutants that were previously undetected or considered as risk free. Nevertheless, the development of highly sensitive analytical techniques has allowed the establishment of methodologies for the

determination of these compounds. Among the emerging contaminants, brominated flame retardants, chlorinated paraffins, petrol additives, new DBPs, and short-chain alkylphenol ethoxylates can be analyzed by GC.

Brominated flame retardants are widely used as polymer additives in plastics, electric appliances, and textile and polyurethane foams. Some of the technical flame retardant products contain brominated organic compounds, including polybrominated biphenyls (PBBs) and polybrominated diphenyl ethers. These compounds are structurally similar to PCBs and, therefore, their chemical properties, persistence, bioaccumulation, and distribution in the environment follow similar patterns. Moreover, they have potential endocrine disrupting properties and there are concerns over their exposure health effects.

The analysis of PBBs is more difficult than that of PCBs mainly because the higher brominated compounds can decompose during GC analysis at high temperatures. Generally, GC with nonpolar stationary phases such as 5% phenyl methylpolysiloxane is used for congener-specific determination of PBB in environmental samples. Semiquantitative total-PBB analyses are usually performed because the number of available individual PBB standards is very limited. As highly chlorinated PCBs and PCTs may interfere with low brominated PBBs during GC analysis, ECD is not recommended for detection. MS, especially in NCI, which offers high sensitivity for compounds with four or more bromine atoms, is the technique currently used for the analysis of these compounds. For PBDE analysis long capillary columns (30–50 m) are used with stationary phases such as 5% phenyl methylpolysiloxane and/or 14% cyanopropylphenyl methylpolysiloxane in order to have enough resolution among congeners. Nevertheless, short columns (10–15 m) are proposed for the higher brominated PBDEs, such as BDE209, which shows long retention times and are thermally labile. Both ECD and MS have been proposed as detectors, but co-elution of PBDE congeners with organochlorine pesticides and PCBs which elute together in the same fraction when silica is used for cleanup presents problems when ECD is used. These problems can be solved by MS detection. For LRMS, both EI and NCI have been proposed but NCI provides better sensitivity for the higher brominated compounds (hepta- to decabDEs). A drawback of NCI is the lack of selectivity, since for most of the compounds only the bromine cluster ions ( $m/z$  79 and 81) are monitored. In contrast, EI offers more selectivity and confirmation from the mass spectrum but has a much lower sensitivity. Electron ionization high-resolution MS (EI-HRMS) has the advantage of increased selectivity

and sensitivity, although it requires experienced personnel and is more expensive and labor-intensive than LRMS.

Chlorinated paraffins (CPs) are complex industrial formulations of polychlorinated *n*-alkanes (PACs) with carbon chain lengths between  $C_{10}$  and  $C_{30}$  and a degree of chlorination between 30% and 70%. These compounds are used as additives in cutting fluids, paints, plasticizers, and sealants as well as flame retardants. The analysis of CPs is difficult due to the large number of congeners (a minimum of several thousands) present in the technical mixtures. Generally, nonpolar GC capillary columns such as methylpolysiloxane and 5% phenyl methylpolysiloxane are used and the chromatograms show a characteristic broad profile of unresolved peaks. This profile is used for quantitative analysis, as can be seen in **Figure 4**, where the chromatogram of a water sample containing short-chain CPs is given. CPs are usually detected by ECD or by electron-capture negative ion MS at both low and high resolutions.

Methods including headspace, purge and trap, or SPME combined with GC have been used to measure methyl *tert*-butyl ether (MTBE) in ground water and surface water. MTBE has been used as a petrol additive since its introduction in 1979, and water contamination is due to leaking underground storage gasoline tanks and discharges from fuel from boats. This compound is responsible for odor and taste problems in drinking water. GC with nonpolar stationary phases and FID, photoionization, and MS detection systems are the most frequently used methods for the analysis of this compound.

**Figure 4** SPME-GC-ECD chromatogram of a water river sample. Elution time of short-chain chlorinated paraffins is indicated in the chromatogram. Experimental conditions: GC column: DB-5 (J&W Scientific) 30 m  $\times$  0.25 mm ID, 0.25  $\mu$ m film thickness. (Reprinted with permission from Castells P, Santos FJ, and Galceran MT (2003) Solid-phase microextraction for the analysis of short-chain chlorinated paraffins in water samples. *Journal of Chromatography A* 984: 1–8.)

DPBs beyond those that are currently regulated (Table 2) are becoming important. For instance, brominated DBPs are now being recognized as toxicologically important because they are proving to be much more carcinogenic than their chlorinated analogs. Moreover, preliminary studies suggest that iodinated compounds may be more toxic than their brominated analogs. These compounds are formed when relatively high concentrations of bromide and/or iodide are present in source waters, as frequently happens in coastal cities. Specific DBPs of current interest are bromo- and iodo-THM, cyanogen bromide, bromonitromethanes, and brominated forms of 3-chloro-4-(dichloromethyl)-5-hydroxy-2-(5H) furanone (MX). The methods of analysis of these compounds are similar to those used for the regulated DBPs but some of them require special GC analytical conditions because they are thermally unstable and decompose under the commonly used injection temperatures in GC analysis.

Other compounds that have received considerable attention in the last few years are alkylphenol polyethoxylate (AP $n$ EOs,  $n$ =number of ethoxy units) degradation products such as octyl- and nonylphenols and the corresponding mono- and diethoxylates. These compounds have been included in the list of priority substances in the field of water policy and amending of the EU because of their widespread use and potential endocrine disruption capacity. Short ethoxylated chain AP $n$ EOs, octyl and nonylphenols, their carboxylate metabolites, and also the halogenated derivatives that are formed during chlorine disinfection can be analyzed using GC after derivatization. Capillary GC with nonpolar stationary phases, e.g., 5% phenyl methylpolysiloxane (DB-5), coupled to MS can be used for the analysis of these compounds. As an example, Figure 5 shows a GC–MS total-ion chromatogram of methylated nonylphenol, nonylphenol ethoxylates, and their acidic metabolites in a river water sample.

**Figure 5** Headspace-SPME–GC–MS single-ion chromatograms of derivatized compounds from river water entering water treatment plant. NP: nonylphenol, NP1EO: nonylphenol monoethoxylate, NP2EO: nonylphenol diethoxylate, NP1EC: nonylphenoxyacetic acid, NP2EC: nonylphenoxyethoxyacetic acid. Experimental conditions: GC column: DB-5 MS, 30 m  $\times$  0.25 mm ID, 0.25  $\mu$ m film thickness. MS analyzer: quadrupole, operating in SIM mode. ## Introduction

Following ultraviolet–visible spectrophotometry and infrared (IR) spectroscopy, gas chromatography (GC) was one of the first instrumental techniques to help in solving forensic science problems. The early very successful applications included the determination of blood alcohol by direct injection of blood or serum, and the detection and identification of petroleum products in debris from arson cases in 1958/59. The breakthrough of GC in these areas and in drug analysis was an event of the 1960s and the 1970s.

The routine use of capillary columns for much better separation compared with packed columns was achieved during the 1980s and the 1990s, thus allowing, for example, much better discrimination for the forensic comparison of samples. Other practical improvements during that time included the automation of GC instruments, from the injection of samples using autosamplers to the overall instrument control and evaluation of results by modern personal computers. Recent advances in GC have been achieved in combining the very successful technique of headspace solid-phase microextraction (SPME) as sample preparation method with the GC analysis. Especially in arson investigations, this solvent-free technique, with the ability for field sampling, has fundamentally changed the workup and detection of ignitable solvents. Other new improvements include the introduction of the Fast GC technique, which means the reduction of separation times for

multicomponent mixtures from hours to minutes by using smaller diameter, shorter capillary columns with the necessary adjustments of the carrier gas flow and using electronic pressure control.

Today, GC is still one of the most widely used instrumental techniques in forensic science laboratories around the world, now mostly in combination with a mass spectrometer as the substance-specific detector. The types of specimens analyzed range from gases (e.g., cyclopropane) to polymers (e.g., plastics), which can be made amenable to GC through pyrolysis.

## Alcohol in Blood

The gas chromatographic determination of ethanol in blood has been a well-established method since the 1960s. It is also today one of the classical examples for the application of GC in the forensic sciences. The early introduction of headspace sampling has simplified greatly sample preparation, injection, and analysis (no contamination of the column and the injector by blood residues). The automation of the whole procedure was also achieved very early and today with coupled automated data-handling systems the requirements of standard quality control (QC) procedures can be fulfilled in a very good manner. Flame ionization detection is the favorite detection technique. The headspace gas chromatographic procedure has been proven as a highly specific method with good precision and reproducibility. Typical results of the reproducibility for within-run and between-run coefficients of variation are <1.5 and <2.5%, respectively.

Scientific developments in gas chromatographic analysis in the 1980s and the 1990s concentrated on the detection and determination of congeners from

## Introduction

Following ultraviolet–visible spectrophotometry and infrared (IR) spectroscopy, gas chromatography (GC) was one of the first instrumental techniques to help in solving forensic science problems. The early very successful applications included the determination of blood alcohol by direct injection of blood or serum, and the detection and identification of petroleum products in debris from arson cases in 1958/59. The breakthrough of GC in these areas and in drug analysis was an event of the 1960s and the 1970s.

The routine use of capillary columns for much better separation compared with packed columns was achieved during the 1980s and the 1990s, thus allowing, for example, much better discrimination for the forensic comparison of samples. Other practical improvements during that time included the automation of GC instruments, from the injection of samples using autosamplers to the overall instrument control and evaluation of results by modern personal computers. Recent advances in GC have been achieved in combining the very successful technique of headspace solid-phase microextraction (SPME) as sample preparation method with the GC analysis. Especially in arson investigations, this solvent-free technique, with the ability for field sampling, has fundamentally changed the workup and detection of ignitable solvents. Other new improvements include the introduction of the Fast GC technique, which means the reduction of separation times for

multicomponent mixtures from hours to minutes by using smaller diameter, shorter capillary columns with the necessary adjustments of the carrier gas flow and using electronic pressure control.

Today, GC is still one of the most widely used instrumental techniques in forensic science laboratories around the world, now mostly in combination with a mass spectrometer as the substance-specific detector. The types of specimens analyzed range from gases (e.g., cyclopropane) to polymers (e.g., plastics), which can be made amenable to GC through pyrolysis.

## Alcohol in Blood

The gas chromatographic determination of ethanol in blood has been a well-established method since the 1960s. It is also today one of the classical examples for the application of GC in the forensic sciences. The early introduction of headspace sampling has simplified greatly sample preparation, injection, and analysis (no contamination of the column and the injector by blood residues). The automation of the whole procedure was also achieved very early and today with coupled automated data-handling systems the requirements of standard quality control (QC) procedures can be fulfilled in a very good manner. Flame ionization detection is the favorite detection technique. The headspace gas chromatographic procedure has been proven as a highly specific method with good precision and reproducibility. Typical results of the reproducibility for within-run and between-run coefficients of variation are <1.5 and <2.5%, respectively.

Scientific developments in gas chromatographic analysis in the 1980s and the 1990s concentrated on the detection and determination of congeners from

alcoholic beverages in blood, serum, and urine. After thorough studies in this complex area, the assessment of the type and amount of consumed alcoholic beverage is possible with some limitations, particularly in cases of drinking after a forensically relevant event. As always in the forensic sciences, much background information concerning the drinking event, the type of the suspected consumed alcoholic beverage (for example, the original sample found at a suspect's home), and metabolism of special congener compounds is necessary for applications of proper expertise in this field. Differences in the individual absorption rates of alcohol also have to be taken into account. 1-Propanol and isobutanol are the most important congener alcohols and need to be quantified in each analysis. It has to be considered that some beverages (like vodka and grain spirit) contain no forensically relevant concentrations of congeners and that through nonaseptic handling 1-propanol and isobutanol can be produced during the preparation and storage of blood samples, taken for blood alcohol analysis. Capillary GC with microheadspace sampling and the use of different internal standards for compensation of matrix effects has proved effective for good quantification of important congeners. The use of the flame ionization detector (FID) is part of this basic technique, but today as a second indispensable detection mode the use of a mass spectrometer is highly recommended to identify additional compounds that may be used as markers. **Figure 1** shows, as an example, chromatograms of congener compounds analyzed on two different capillary columns with an FID being used for detection. A mass spectrometer is recommended for the detection of additional compounds. These compounds could then be added to a retention index list.

The well-established GC methods for blood ethanol determination are today the Gold Standard in cases, where, for instance, results from the quantitative breath-alcohol analyzer used for evidential purpose are challenged. The basis for this importance is an overwhelming amount of data available from the GC tests and the rigorous QC scheme for precision and accuracy testing.

## Drug Determinations

A major work for all forensic science laboratories is directed to the analysis of drugs of abuse. GC plays a prominent role in analyzing these exhibits, both for identification of the particular drug (qualitative analysis) and for the determination of the amount of pure drug in the sample (quantitative analysis).

One of the advantages of using capillary GC in the determination of drugs is that a wide variety of

**Figure 1** Gas chromatograms of an aqueous calibration mixture for analysis of congeners of alcoholic beverages in blood after splitless headspace sampling. Left: capillary column 60 m  $\times$  0.32 mm i.d. coated with DB 1701, film thickness 1  $\mu$ m. Right: capillary column 60 m  $\times$  0.32 mm i.d. coated with CP-Sil 8-CB, film thickness 2.8  $\mu$ m. Carrier gas 1.5 bar (150 kPa) hydrogen; manual injection of 0.5 ml, splitless 6 s, then 50 ml min<sup>-1</sup> split flow. Concentration of congeners  $\sim$ 0.8 mg l<sup>-1</sup>, methanol  $\sim$ 5 mg l<sup>-1</sup>, ethanol  $\sim$ 1.6 g l<sup>-1</sup>. Peaks: 1, acetaldehyde; 2, methanol; 3, ethanol; 4, acetone; 5, 2-propanol; 6, *t*-butyl alcohol; 7, 1-propanol; 8, ethyl acetate; 9, ethyl methyl ketone (2-butanone); 10, 2-butanone; 11, isobutyl alcohol (2-methyl-1-propanol); 12, 1-butanol; 13, 3-methylbutanol; 14, 2-methylbutanol. (Reproduced with permission from Wolf M, Weiler JP, Urban R, and Tröger HD (1987) *Zur Begleitstoffanalytik 2. Mitteilung: Aspekte der quantitativen Bestimmung. Blutalkohol* 24: 378–390; © Bund gegen Alkohol und Drogen.)

chemically different compounds can be chromatographed in the same system. This has led, for instance, to the very comprehensive and successful approach for the identification of drugs and poisons using capillary GC and mass selective detection by Pfleger, Maurer, and Weber resulting in their famous collection of mass spectra and gas chromatographic data. The unique separation efficiency of this technique is also essential for the detailed analysis of illicit drugs as required for the comparison of different samples and seizures. Today, most GC applications in this field use capillary columns with nonpolar or slightly polar phases and mass selective detection and/or FID. The FID is well suited for quantification of the separated compounds because it has a linear response over seven orders of magnitude, it is very stable, and the response is reproducible. Normally, quantification is done using the internal standard method. Nitrogen-selective detection is sometimes used in forensic toxicology. The new types of mass spectrometers like the ion-trap quadrupole instruments are also used as detectors because they enable controlled experiments of further fragmentation of some key ions in order to obtain an even more specific and sensitive method. The electron-capture detector (ECD), as an example of not only a selective and sensitive but also a more complicated detector to

operate, is only applied for special tasks, such as the detection of trace impurities in illicit drug samples after derivatization with heptafluorobutyric anhydride. Also, only a few applications were reported for the coupling of GC with an IR spectroscopic detector. This combination was used for the differentiation of isomers of amphetamine derivatives because here mass spectrometry (MS) alone has some limitations to unequivocally identify the specific isomer.

In spite of the fact that the basic GC techniques used are much the same for analysis of solid forms and for the determination of drugs in biological specimens like body fluids and hair, the special needs for adequate sample preparation and adjustments to the different matrices have led to distinct developments in the two areas and are discussed separately here.

### Drugs in Solid Form

Large amounts of illicit drugs seized by police and customs are normally in solid form, such as powders, tablets, capsules, and those impregnated on paper. The main requirements for law enforcement and the courts are to identify correctly the material and in many cases to report a percentage purity of the active and controlled compound, e.g., diacetylmorphine in illicit heroin. For most drugs of abuse GC is well suited to fulfill both these tasks, but other chromatographic techniques also have their role in the forensic analysis of drugs. Thin-layer chromatography (TLC), for instance, is generally cheaper and easier to operate, whereas liquid chromatography (LC) is suitable in cases where the compound in question can thermally decompose during GC. Another modern alternative to GC and LC is the use of capillary electrophoresis, for instance, in cases to determine the enantiomeric composition of certain drugs.

Derivatization is mostly used if the drug does not chromatograph well without chemical modification and in cases where better separation of the derivatized substances can be expected. Derivatization is also a good approach in cases where a complex mixture of original drug ingredients, added pharmacologically active compounds (adulterants), and inactive substances (diluent) such as sugars have to be separated. **Figure 2** shows an example from our laboratory where silylation with *N*-methyl-*N*-trimethylsilyltrifluoroacetamide (MSTFA) was used to identify and quantify the opium alkaloids and derivatives and the 'cutting' substances in an illicit heroin sample in one analytical run. The silylation conditions used with heroin, crude morphine, and opium samples help to avoid many possible problems such as transacetylation, adsorption, and different responses for salt and base. The alkaloid derivatives from acetylcodeine

**Figure 2** Gas chromatogram of an illicit heroin sample. Conditions: fused-silica capillary column 25 m  $\times$  0.32 mm i.d. coated with OV-1 cb; carrier gas 0.7 bar (70 kPa) hydrogen; split  $\sim$  1:15, make-up gas argon at 18 ml min<sup>-1</sup>; oven temperature program 150–280°C at 9°C min<sup>-1</sup>, then 0.5 min isothermal; injector/detector (FID) temperatures 250/280°C. Sample silylated with MSTFA. Peaks: 1, nicotinamide-TMS; 2, meconin; 3, caffeine; 4, glucose-TMS; 5, phenobarbital-TMS; 6, methaqualone; 7, acetylcodeine; 8, acetylthebaol; 9, morphine-TMS; 10, 6-O-acetylmorphine-TMS; 11, diacetylmorphine; 12, papaverine; 13, phenolphthalein-TMS; 14, narcotine; S, tetracosane (internal standard) (TMS, trimethylsilyl derivative).

(peak 7) to diacetylmorphine (peak 11) in **Figure 2** are better separated with derivatization than without using this sample preparation step.

Cocaine can also be analyzed well by GC. Here again silylation can help to achieve good separation of major, minor, and trace components of the illicit cocaine samples and was therefore proposed as early as in 1973 by Moore. The sample preparation procedure used in our laboratory for the analysis of heroin and cocaine starts by dissolving the sample in chloroform. Then a mixture of MSTFA and pyridine is added and allowed to react at 80°C for 10 min. After that the solution is chromatographed directly.

GC is also the predominant technique to analyze cannabis products like marijuana and hashish. Here, the determination of the 'total tetrahydrocannabinol (THC) content' or the 'available THC content' is useful, because THC-acid is present in these samples as well as THC. The application of direct GC is the technique of choice for this determination, after extraction from the plant material with a suitable solvent such as methanol or chloroform. Methaqualone and phencyclidine and their analogs are other drug compounds well suited for gas chromatographic analysis. For some benzodiazepines, thermal

decomposition during GC has been reported. For barbiturates and psilocybin, derivatization has to be applied. Lysergic acid diethylamide also cannot be easily analyzed by GC.

The detailed analysis of drug samples, named 'profiling', for the purpose of sample comparison and/or identification of key impurities, characteristics of certain routes of synthesis, or used in origin-related studies ('markers') was much improved by the application of capillary columns in GC. The state-of-the-art applications of this high-resolution technique can be divided into two approaches. In the first, the sample is analyzed by capillary GC without selective extraction or special pretreatment. In the second, the classic liquid/liquid extraction or similar steps like solid-phase extraction (SPE) are used to pre-separate the characteristic impurities (congeners, by-products of synthesis, etc.) from the bulk drug matrix to allow for their detection in trace amounts. **Figure 3** shows the trace impurity profiles (drug signatures) of two illicit heroin samples after toluene extraction from  $0.5 \text{ mol l}^{-1}$  sulfuric acid. The gas chromatographic profiles are stored in a database for retrospective comparisons, using 14 characteristic impurity compounds as descriptors. By searching the database with the help of a statistical method these two samples could be grouped together.

In general, the optimization of an appropriate extraction method (e.g., with respect to solvent type, pH value, volumes) in combination with the selection of the characteristic impurity compounds is critical for a good reproducibility of the whole procedure. This proven reproducibility is the basis of the successful application of this approach. After groundbreaking work on amphetamine produced by the Leuckart synthesis, heroin, and cocaine in the 1970s and the 1980s, the last few years have seen a further refinement of the developed profiling GC procedures for these drugs and an application to the investigation of amphetamine derivatives like methamphetamine and 3,4-methylenedioxymethamphetamine (MDMA), the main ingredient of the so-called 'ecstasy tablets'. The quantitation of MDMA in illicit preparations is normally done by LC. But for detailed studies directed to the identification of key impurities for identification of the route of synthesis and for the comparison of samples the application of capillary GC is preferred. **Figure 4** shows chromatograms of minor and trace components from three typical MDMA tablets. The peak areas of the selected impurity substances form the basis for the comparison of samples.

In the most recent developments SPME in combination with capillary GC and GC-MS is used for the characterization of volatile impurities in illicit

**Figure 3** Sample comparison via capillary gas chromatographic impurity profiles of two seizures of Southwest Asian heroin base. Note the dilution of the sample at the bottom with caffeine (peak no. 2). Peaks: 1, meconin; 2, caffeine; 3, acetylthebaol; 4, (*E*)-*N*-acetylanhydronarceine; 5, (*Z*)-*N*-acetylanhydronarceine; S, tetracontane (internal standard). A harmonization study for retrospective comparisons. *Forensic Science International* 114: 67–88; © Elsevier Ireland Ltd.)

amphetamine, methamphetamine, 4-methoxyamphetamine, and MDMA samples. In this solvent-free sample preparation technique, a fiber coated, for instance, with polydimethylsiloxane (PDMS) or polyacrylate is used to concentrate the analyte. Normally, the fiber is then put into the injector of the gas chromatograph and the compounds are thermally desorbed to the column. In general, these profiling methods have demonstrated their practical value for the forensic comparison of illicit drug samples.

### Drugs in Biological Specimens

The most prominent biological samples used for testing for drugs of abuse are urine, blood, hair, and saliva. Drugs can also be detected in many other biological specimens, such as sweat, vitreous humor, and autopsy material such as liver in general

**Figure 4** Typical gas chromatographic impurity profiles of different MDMA samples. The big peak at retention time 12.2 min (after peak no. 12) corresponds to MDMA. Peaks: 7, 3,4-methylenedioxy-*N*-methylbenzylamine; 10, 3,4-methylenedioxyphenyl-2-propanone; 12, 3,4-methylenedioxy-phenyl-2-propanol; 16, *N*-ethyl-3,4-methylenedioxyamphetamine; 17, *N,N*-dimethyl-3,4-methylenedioxyamphetamine; 18, 1-(1,2-dimethyl-1-azacyclopentyl)methyl-3,4-methylenedioxybenzene; 21, caffeine; 24, palmitic acid; 28, stearic acid. (Reproduced with permission from Palhol F, Boyer S, Naulet N, and Chabrilat M (2002) Impurity profiling of seized MDMA tablets by capillary gas chromatography. *Analytical and Bioanalytical Chemistry* 374: 274–281; © Springer-Verlag.)

toxicological analysis for the detection of poisons and other unusual substances.

The key element that sets analysis of drugs in biological specimens like urine and plasma apart from the analysis in solid form is the necessity for the appropriate sample preparation. This involves isolation and, if necessary, cleavage of conjugates and/or derivatization. Traditionally, liquid–liquid extraction is used for isolation. However, in the last 25 years SPE has been introduced as a very efficient technique. Its main advantages after careful selection and testing with various drugs are that higher selectivity is achieved, cleaner extracts can be obtained, and this type of sample preparation can be easily automated. The last development in this area was the application of SPME to the investigation of biological samples such as whole blood, plasma, urine, and hair for illicit drugs and poisons. The analytes included are, for instance, amphetamine and derivatives like methamphetamine and MDMA, cocaine, THC, and benzodiazepines.

The state-of-the-art technique for the analysis of illicit drugs in body fluids is GC–MS, mostly using

mass selective detectors. Recommended guidelines for forensic GC–MS procedures in toxicology laboratories analyzing biological samples have been published to establish a high standard of practice. A good-quality, full-scan mass spectrum and the analyte's expected retention time in the gas chromatogram provide the best criteria for a sure forensic identification of drugs of abuse, e.g., in the context of urine testing. Duplicate specimens should allow an independent analysis when the results of testing of the first sample are challenged. For support of the systematic toxicological analysis of drugs, poisons, pesticides, and their metabolites, the excellent collection of mass spectra and GC data from Pfleger, Maurer, and Weber is very helpful.

While biological fluids allow the detection of drugs after a recent misuse (normally a few days), hair is an interesting substrate for the investigation of chronic drug abuse (over periods up to 6 months and 1 year). For detection of drugs in human hair again GC–MS is the most important confirmation technique in connection with immunoassay screening. Careful consideration with hair must be given to the possibility of external contamination by drugs of abuse, because not all wash procedures are effective in removing the contaminating substances. The detection of heroin and its first biotransformation product, 6-acetylmorphine, in hair by GC–MS was used to differentiate heroin exposure from other sources of opiates, for example, licit codeine preparations or poppy seeds.

## Arson, Explosives, and Propellant Residues

After an investigation of a scene of fire or explosion, debris samples are frequently collected and sent to the forensic science laboratory for analysis of the presence of an accelerant or residues of explosives.

GC was introduced very early as the technique of choice for the detection and identification of accelerants in debris from arson cases because of its high selectivity and sensitivity. But to use the full potential of the technique the methods of recovery of traces of common accelerants from fire debris had to be developed and adjusted. The used methods include solvent extraction, direct headspace analysis, and enrichment by adsorbent-based techniques. In the past, the most common concentration steps prior to the analysis have been (heated) headspace direct injection using a gastight syringe for analyte collection and GC injection or headspace adsorption techniques, mostly using charcoal followed by carbon disulfide (CS<sub>2</sub>) elution. Some of these procedures have been quite effective and are standardized by

**Figure 5** Gas chromatographic comparison of gasoline component recovery by headspace SPME sampling using a Carboxen/PDMS fiber. Top: results obtained by direct injection of gasoline. Middle: headspace sampling by SPME over neat gasoline. Bottom: headspace sampling by SPME of gasoline on carpet. Peaks: 1, toluene; 2, 3-methylheptane; 3, octane; 4, ethylbenzene; 5, 1,3- and 1,4-dimethylbenzene; 6, 1,2-dimethylbenzene; 7, nonane; 8, propylbenzene; 9, 1-ethyl-(2 or 3)-methylbenzene; 10, 1,2,5-trimethylbenzene; 11, 1-ethyl-2-methylbenzene; 12, 1,2,4-trimethylbenzene. (Reprinted with permission from Lloyd JA and Edmiston PL (2003) Preferential extraction of hydrocarbons from fire debris samples by solid phase microextraction. *Journal of Forensic Sciences* 48: 130–134; © ASTM International.)

American Society for Testing and Materials. A new and very successful development of the last 10 years was the introduction of headspace SPME for sampling of arson accelerants. The method uses a fiber coated, for instance, with Carboxen/PDMS for concentration of ignitable liquids from fire debris samples. SPME has a lower detection limit for some analytes, it is a fast technique, and is easy to use. So, for instance, the older procedure with 16 h of sampling using charcoal strips can be replaced by an SPME method that lasts only 10 min. **Figure 5** shows an example where the chromatogram from direct injection of gasoline is compared with the headspace sampling by SPME over neat gasoline and of gasoline on carpet. The result was that the Carboxen/PDMS fiber preferentially adsorbs the aromatic hydrocarbons quite effectively. In SPME, the thermal analyte desorption mode, used normally to introduce the substances from the SPME fiber to the gas chromatograph, can be replaced by solvent-based desorption. Here again, elution with  $\text{CS}_2$  is most effective and the extracts can be archived and used for repeated automated analysis.

As column coatings for the capillary columns, used in the gas chromatographic analysis of arson accelerants, nonpolar phases of the methyl silicone type

are preferred, because hydrocarbons are eluted in boiling-point order. Capillary GC, mostly coupled now to a mass spectrometer, is an excellent technique for the comparison of unchanged automotive gasoline. By comparing the relative concentrations of hydrocarbons it was found that most of the discriminating information is contained in the fraction with a volatility ranging from *n*-pentane to *n*-octane. When comparing gasoline recovered from a fire scene with a possible source, several factors must be considered, including the variability introduced by the recovery method, evaporative losses from the gasoline, possible contamination by pyrolysis products (mainly aromatic hydrocarbons), and other alterations of the recovered gasoline by chemical and physical interactions. Typical examples of interfering organic compounds include lanolin from carpet underlay, terpenes from wood samples, and styrene, toluene, and benzene from polystyrene or other polymeric components of construction and furnishing materials. GC–MS can help to rapidly identify background pyrolysis products and help to distinguish these matrix interferences from common accelerants. As a result of a detailed study in arson cases it was concluded that a comparison by capillary GC is extremely useful in eliminating the possibility of a common origin of two samples, but it is very difficult to determine conclusively that two samples have a common origin.

In conclusion, good discrimination can be achieved of unchanged and weathered (altered) gasoline, gas oils (diesel), and crude oils by using GC with capillary columns. For the comparison of unchanged gasoline samples the use of the extracted ion chromatogram technique in GC–MS from the elution region between *n*-pentane and *n*-octane is very useful. The sampling for this part of the gas chromatogram can easily be achieved with the SPME technique using a fiber coated with PDMS. The intensities of characteristic gasoline compounds in the ion chromatograms can be compared visually and evaluated with statements like ‘smaller’, ‘bigger’, etc. These data can be stored in a database, together with other information concerning the gasoline sample, and are used for retrospective comparisons. The prerequisites for the successful application of this method using the extracted ion chromatograms is that the whole analytical procedure be regularly checked by ‘calibration gasoline’ and the comparison investigations be performed under the exact same conditions.

The detection of explosives and propellants in postblast residues and in hand swabs from persons suspected of firing a gun or handling explosives is extremely important for the success of a prosecution. The role of GC for the analysis of these polar and

sometimes thermally unstable compounds is limited, and therefore other chromatographic techniques such as LC, TLC, and ion chromatography, and spectroscopic techniques like IR are also often used. However, modern fused-silica column capillary GC using very sensitive special detectors such as the ECD and the thermal energy analyzer enables nanogram to picogram sensitivity to be achieved for many explosive substances. Capillary GC-MS is the other very useful analytical combination for the unequivocal identification of explosives. Trinitrotoluene and dinitrotoluene isomers, cyclotrimethylene trinitramine, pentaerythritoltetranitrate, tetra, cyclotetramethylene tetranitramine, nitroglycerine, and ethylene glycol dinitrate have been detected successfully in this respect. Modern SPE is one of the proven techniques for efficient and selective sample clean-up and concentration. SPME was evaluated for the recovery of explosive residues from aqueous samples and real postexplosion solid debris samples, also as a field sampling device.

Pyrolysis GC (Py-GC) has been used for the identification and comparison of propellants. Smokeless powder propellants were analyzed by pyrolysis capillary GC-MS, and main organic propellant constituents together with additives could be detected and used as criteria for comparison. However, the standard technique for the examination of gunshot residues is scanning electron microscopy.

## Other Applications

GC in a forensic context has been used for the analysis of many other specimens besides the major groups reported above. The prerequisite is that the analytes have an organic chemical nature. Closely related to drug misuse is the abuse of organic solvents for sniffing among adolescents. Toluene, contained in paint thinner and glue for example, is the most commonly misused organic solvent. Other misused volatile substances include aerosols such as propane and butane and the group of halogenated hydrocarbons, alkyl nitrites, lighter fuels, and gasoline. Volatile solvents are central nervous system depressants and therefore dangerous in connection with road traffic for instance.

Generally, GC is a very suitable technique for the analysis of these volatile substances and the definitive proof of exposure to them is their detection in biological fluids and tissues. All the commonly abused solvents can be detected in the headspace from 200  $\mu$ l of blood. Toluene could be detected by MS in the breath of known glue sniffers up to 4 days after the last episode. GC and GC-MS were used to determine toluene in various tissues and blood in a

fatal case of oral ingestion of toluene. The toluene levels determined in postmortem blood, lung, liver, and brain from a toluene poisoning case that happened during painting were not high enough to be definitely lethal. But they were high enough to anesthetize the central nervous system. This is in agreement with general findings that death normally results from a dangerous situation existing while the person is intoxicated. Even cyclopropane gas taken from a cylinder of cyclopropane in a university laboratory was identified by a headspace GC-MS procedure as the abused substance causing the death of a student. Alkyl nitrites have been hydrolyzed with methanol to their respective alcohols, which can be identified easily by GC. Other toxic chemicals, such as carbon monoxide, hydrocyanic acid, chloroform, and tetrahydrofuran in blood and body material, have been identified and determined by headspace GC and GC-MS.

Nonvolatile organic substances such as polymers, car paints, hair, etc., have to be subjected to pyrolysis before GC separation of the products formed can be achieved. Normally, a suspect polymeric specimen is compared with a control sample in order to establish common origin. The high resolution and inertness of capillary columns offers enhanced discrimination and much greater column-to-column and instrument-to-instrument reproducibility. The combination of Py-GC with MS (Py-GC-MS) added the most valuable mass selective detection to the retention time parameter and brought a major step forward in generating objective data for sample comparisons. Databases for retrospective searching can be generated based on the criteria of certain characteristic masses and the retention time combined with peak area. Py-GC-MS is now routinely used for the examination of the organic components of paint, especially for automobile paint, plastics, and synthetic fibers. Other published applications of Py-GC and Py-GC-MS include the characterization of adhesives (e.g., as used in the construction of explosive devices), photocopier toner type, trace rubber residues (e.g., from shoe soles and tyres), plastic automobile bumper bars and light lenses, phenolic resins, polymer additives, polyurethane foams, tapes, and clingfilms. Fourier-transform IR spectroscopy is the other well-established technique for the analysis of these polymeric products.

The lachrymators 2-chloroacetophenone and *o*-chlorobenzylmalonitrile in tear gas, bank security devices, etc., have been identified by GC-MS. Capillary GC has been utilized to discriminate waxes and greases in cosmetic materials such as lipsticks submitted in forensic casework. For applications of this sort the recent improvements in high-temperature GC are very useful.

A dramatic decrease of the time of analysis can be achieved by using narrower columns combined with an adjusted improved electronic pressure control system. As today in most forensic science laboratories the procedures developed with the normal capillary GC instrumentation are part of a quality management system, a major change using the possibilities of 'Fast GC' requires a new validation. This, together with the high level of performance reached during the last 15 years in capillary GC, may to some extent slow down the process of innovation in this area.

This article is reproduced from the previous edition, pp. 1907–1913, © 1995, Elsevier Ltd., with an updated Further Reading list supplied by the Editor.

Any account of gas chromatography (GC) should include the analysis of petroleum and petroleum products, since the petroleum industry has made a major contribution to the development of the technique. The two main reasons are that the mixtures encountered are frequently of complex composition and that hydrocarbon mixtures are extremely

difficult to separate by any other analytical technique. These statements are generalizations and there are numerous exceptions, but they do not alter the main premise. The mixtures encountered range from permanent gases and low-boiling-point hydrocarbons to intractable polymeric materials containing compounds with a relative molecular mass of well above 1000. In addition to the wide range in molecular mass, there is also a broad range of molecular types and sulfur, nitrogen and organometallic compounds are present in significant amounts in crude oils. Ethers and alcohols are present in unleaded gasoline; nitrogen, phosphorus, sulfur and halogen compounds are used as lubricating oil additives, and

C<sub>16</sub>–C<sub>20</sub> fatty acids are essential components of greases. The topics discussed below have been chosen as illustrations and the article cannot be considered to be comprehensive.

## Gases and Light Hydrocarbons

The analysis of mixtures of nitrogen, oxygen, carbon dioxide, and hydrocarbon gases up to C<sub>8</sub> is one that the industry is required to carry out for fiscal reasons, which means that the pertinent Institute of Petroleum method (IP 345/80) has been the subject of stringent trials. This type of sample may seem, at first sight, to be a relatively simple mixture to analyze, until it is examined more closely. The first problem is that the separation of oxygen and nitrogen often requires operation of the column at subambient temperatures. The analysis is specifically concerned with so-called 'associated gas', i.e., the gas in equilibrium with crude oil at around atmospheric pressure. Under these conditions the concentrations of the C<sub>6</sub>–C<sub>8</sub> hydrocarbons are below the lower limit of detection of the thermal conductivity detector (TCD) and it is necessary to employ a TCD followed by a flame ionization detector (FID). The TCD detects the permanent gases and the C<sub>1</sub>–C<sub>4</sub> hydrocarbons and the FID detects all the hydrocarbons up to C<sub>8</sub> but not the permanent gases. The two sets of signals are linked through the ethane peak, which gives a large response with both detectors (Figure 1).

Apart from the use of two detectors in series, this analysis is unusual in that it is effected by gas–solid chromatography (GSC) on a porous polymer packing and the column is temperature programmed from –50°C to +240°C at 15°C min<sup>–1</sup> with an initial isothermal period of 2 min and a final isothermal

period of 10 min. The analysis is of the headspace gases above the crude oil and, therefore, the sample does not contain high-boiling-point compounds. On account of this, and the fact that the separation is by GSC rather than gas–liquid chromatography, the method is extremely robust and can be carried out in very isolated locations provided that liquid nitrogen is available for the subambient starting temperature that is required for the separation of nitrogen from oxygen. There is no oxygen in the crude oil and the separation is required only if there has been an ingress of air during sampling. If this possibility can be eliminated, the temperature programme can be carried out from 20°C, which can be readily attained with carbon dioxide coolant rather than liquid nitrogen. The analysis time can also be shortened from about 32 min to 25 min, with a bigger saving in the turn-round time (the time between each analysis).

The alternative to this method is to use column switching so that the permanent gases pass through a column containing a polymer bead stationary phase that does not separate them and then on to a column containing a molecular sieve that does. After the permanent gases and methane and ethane have left the first column, the exit of this column is switched to an FID to monitor the separation of the hydrocarbons. The advantages of this approach are that subambient programming is not required and that the analysis turn-round time can be substantially reduced. The disadvantage is that it depends on the reliability of the switching valves over many operating cycles, so that it is potentially less robust than the first method. Under normal laboratory conditions, column switching is a well-known and commonly used technique. Another example of column switching is described more fully later.

**Figure 1** Typical chromatogram of associated natural gas using thermal conductivity (TCD; upper curve) and flame ionization (FID; lower curve) detection. (From IP 345/80, courtesy of the Institute of Petroleum.)

## Gasoline Analysis

There are few analyses more impressive than that of a finished gasoline by capillary GC. This may be carried out on a stainless steel column 100 m long by 0.25 mm internal diameter coated with squalane and temperature-programmed from 0°C to 90°C at 5°C min<sup>–1</sup>. Pressure programming with helium carrier gas is used from an inlet pressure of 5 psi to 40 psi since squalane is too volatile to be taken much above 100°C. Analysis under these conditions is capable of yielding over 280 peaks in about 100 min with a turn-round time of 120 min. This means that only about six samples can be analyzed in duplicate every 24 h, which in turn means that automation of the analysis is necessary.

The biggest handicap in increasing the speed of the analysis is the limited thermal stability of squalane. Silicone oils can be used to much higher temperatures, but so far no other stationary phase has been found to be as good as squalane from the point of view of resolution. Another reason for using squalane is that hydrocarbons emerge from such a column mainly in the order of their boiling points, although the effect of molecular shape can be observed in the elution order of multibranched and cyclic molecules as compared with straight-chain molecules. This effect can give a reversal of elution order of up to 5°C but 1–2°C is more common. There is also a large amount of information in the literature on the identification of the emerging peaks by gas chromatography–mass spectrometry (GC–MS).

Hydrogen in place of helium as carrier gas effects a substantial reduction in analysis time, and shortening the column also shortens the time, although there is, naturally, some loss in separation. However, by these means the turn-round time can be reduced to less than an hour, which is more acceptable.

The reason for the considerable effort expended by the petroleum industry on gasoline analysis is the possibility of being able to calculate octane ratings from the full chemical composition determined by GC instead of the standard engine test. By the mid-1970s most of the problems of this approach had been solved except the intractable one of the large effect on octane rating of small concentrations of lead alkyls. The widespread and increasing use of lead-free gasolines, which have their octane rating increased by the addition of relatively large amounts (percentage quantities) of alcohols and ethers, has raised the possibility that this approach is now more likely to be successful.

## Oxygenates in Gasoline

As indicated above, lead-free gasolines currently contain substantial amounts of compounds such as methyl *t*-butyl ether (MTBE) as octane rating improvers, and various methods for the analysis of these compounds in a complex hydrocarbon matrix have been proposed. The method currently favored is the use of an oxygen-specific detector. This is a modified FID first suggested by Schneider and colleagues in 1982. The effluent from the capillary column in the carrier gas (nitrogen with a small amount of hydrogen) passes into a small capillary coil of platinum/iridium electrically heated to 1150°C. Under these conditions, hydrocarbons are cracked, i.e., completely broken down to carbon and

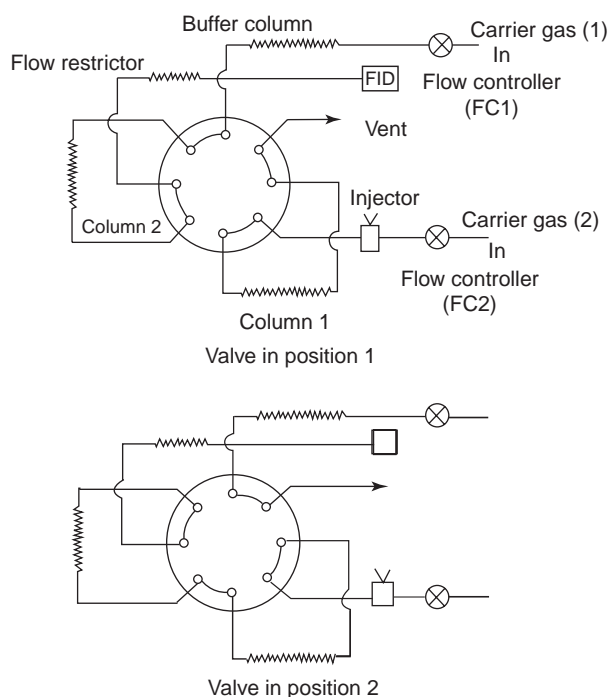

**Figure 2** Oxygenated compounds in an experimental gasoline. O-FID chromatogram. Analysis performed using a 15 m × 0.25 mm i.d. fused-silica capillary column coated with 0.25 μm DB-1, temperature programmed from 40°C to 50°C at 2°C min<sup>-1</sup> then 50°C to 290°C at 30°C min<sup>-1</sup>. (Courtesy of Shell Research Ltd.)

hydrogen. Compounds containing oxygen give carbon monoxide under these conditions. The carbon monoxide passes on to a methanizer, which is a small glass capillary coated with aluminum oxide mixed with nickel catalyst and heated to about 350°C. The methanizer is situated within the jet of the flame detector and the normal hydrogen supply for the flame also serves for the hydrogenation of the carbon monoxide to methane. In spite of this apparently rather complicated approach, the detector (now commercially available and known as the O-FID) works remarkably well with little loss of resolution due to the extra dead volume introduced (Figure 2). The main disadvantage is the relatively poor limit of detection of about 0.1% for oxygenated compounds, since each oxygen atom is equivalent to one molecule of methane; methane has a relatively low sensitivity in the FID, which is a mass detector. Under favorable conditions such as the analysis of small amounts of oxygenated compounds in an essentially pure solvent, this limit may be lowered by one or two orders of magnitude if solvent venting is employed (*see Gas chromatography, specialized detectors*).

This section has been included because it is a good example of the use of selective detectors in petroleum analysis, where the need often arises to analyze for small amounts of heterocompounds in a complex hydrocarbon matrix. Another good example is the use of the flame photometric detector for the determination of small concentrations of sulfur compounds in various plant streams. The analysis of oxygenated compounds can, however, be carried out in a totally different manner using column switching instead of the selective detector.

**Figure 3** Column-switching arrangement for the determination of oxygenated compounds in gasoline. (From IP AX/87, courtesy of the Institute of Petroleum.)

In this method (IP Proposed Method AX/87) the sample is injected, with a suitable internal standard, on to a polar polyester packed column that allows the lower-boiling-point hydrocarbons to elute rapidly. After hydrocarbons up to *n*-heptane have emerged from this first column, the flow through the column is reversed and the effluent is taken to a second column containing Porapak P (a porous polymer bead material), which separates the oxygenates from one another. The oxygenates emerge from this second column before the higher-boiling-point hydrocarbons, which remained in the sample after passage through the first column. To speed up the analysis, the system is then switched back to the original configuration so that the higher boiling hydrocarbons are eluted as an unresolved composite peak. **Figure 3** shows the flow through the system with the 8-port rotary valve in the two positions, and **Figure 4** shows a chromatogram of the oxygenates in a gasoline sample. The buffer column in **Figure 3** is identical to column 1 and is included to minimize flow disturbances on switching the valve. Both columns and switching valve are installed in an oven operating at 150°C. The timing for the valve switching must be determined by the use of calibration blends of *n*-heptane and butanol in *n*-pentane. As in the column-switching method described briefly in the section on gas analysis, these

**Figure 4** Chromatogram obtained with the column-switching system shown in **Figure 3**. (From IP AX/87, courtesy of the Institute of Petroleum.)

are advantages and disadvantages in the column-switching technique. The advantages in this case are the use of packed columns, as opposed to the capillary columns required with the O-FID, which makes quantification simpler and gives a better lower limit of detection. The disadvantages are that the apparatus is complex to set up, and having been set up is completely dedicated to this particular determination. The demands on the switching valve are considerable and operating conditions (column temperature and carrier gas flow rate) must be carefully controlled since otherwise the valve switching times will alter.

## Dilution of Engine Lubricants by Fuels

In petrol and diesel engines for cars, buses, and trucks, the lubricating oil inevitably becomes contaminated to a greater or lesser extent with the engine fuel. The concentration of the fuel in the oil may range from less than 0.1% in a well-maintained engine to greater than 10% in a badly maintained one. Clearly, by the time this sort of concentration has been reached, the lubricant is not performing as it should. By analyzing a sample of the used oil on a short silicone packed column, a bimodal distribution chromatogram is obtained – the first part from the fuel residues and the second part from the lubricating oil. If the used oil is from a gasoline engine, it is very easy to differentiate between the two contributions

to the chromatogram and to quantify the individual contributions. However, if the used oil is from a diesel engine this is much more difficult because the high-boiling-point residues of the diesel fuel overlap the low-boiling-point components of the lubricant. This problem can be solved by running a sample of uncontaminated oil and a sample of 'topped' fuel, that is fuel that has had the low-boiling-point components distilled off. These chromatograms are stored in a computer, which compares them with the chromatogram of the used oil and decides on the allocation of the respective areas due to the fuel and the lubricant. This computer technique has been found to give significantly more accurate results than the arbitrary choice of a split point between fuel and lubricant.

## Crude Oil Analysis

Crude oil analysis is difficult: (1) because of the very wide range of molecular masses involved and (2) because it is impossible to obtain a complete recovery of the high-boiling-point components of the oil. A light North Sea crude will give a recovery of about 85% up to  $C_{42}$ , but this figure could be as low as 50% for a heavy Middle East crude. This problem is tackled by the addition of known amounts of markers to the crude oil sample. If, say, 2% (m/m) of a pure compound that is of low enough boiling point to ensure its complete recovery from the chromatographic analysis is added to the sample, then, from the areas of the peaks obtained, the overall recovery can be calculated. This is standard practice, but in the case of crude oils there are no convenient gaps in the chromatogram where readily available marker compounds will emerge. The solution to the problem is to use known amounts of several (commonly about three) normal paraffins, say 2% each of  $n\text{-}C_{12}$ ,  $n\text{-}C_{14}$ , and  $n\text{-}C_{16}$ . These are present in all crude oils, but they may be used as markers to calculate recovery by measuring the areas due to the known amounts added by subtracting the relevant areas obtained from a sample of the original crude oil. Another convenient well-resolved peak is used as a marker to correct for variations in sample size. Once the recovery has been measured, the analytical results can be expressed in a variety of ways – the amount of an individual compound such as benzene, the amounts of various carbon number groups, e.g.,  $C_5$ ,  $C_6$ ,  $C_7$  present, or as a simulated distillation curve (see below). The average molecular mass of the oil can also be determined as accurately as by other methods and with considerably less effort.

## Simulated Distillation

This technique, which is almost exclusive to the petroleum industry, depends on the fact already stated that, with a nonpolar stationary phase, hydrocarbons emerge more or less in the order of their boiling points. By calibration of the GC with compounds of known boiling point (normal paraffins), the usual time axis of a chromatogram may be converted into a boiling point axis. When an unknown sample is analyzed under identical conditions to those for the  $n$ -paraffin calibration mixture (same column, same carrier gas flow rate, same temperature programme), increments of area at regular short time intervals are measured and plotted against boiling point, i.e., retention time (see Figures 5–7 for a pictorial explanation of the technique).

With modern data-handling systems, the time slices may be as small as 0.1 s but 0.5 s is adequate for packed-column work. The plot of cumulative area vs temperature is a simulated distillation graph. This method has a number of advantages over a true analytical distillation in that it is quicker, requires much less sample, and gives much more accurate values for the initial and final boiling points. In order to minimize any molecular-type effects on retention, such as an aromatic emerging earlier than a paraffin of the

**Figure 5** Temperature scale calibration of the gas chromatogram.

**Figure 6** Chromatogram of a light oil split into equal time slices.

**Figure 7** Simulated distillation curve for the oil.

same boiling point, this method is unique in specifying a column of low efficiency that must not exceed a certain value.

## Oil Spill Identification

There are, fortunately, very few incidents where there is a major spill of crude oil, although lesser incidents involving 1–100 ton quantities are more common. Sometimes the source of the spill is beyond any reasonable doubt, but more often proof of the origin is required for the purpose of compensation claims. There are numerous analytical methods for the identification of crude oils and heavy fuel oils, but in practice they all have limitations. Tentative identification may be made by GC on a low-resolution packed column to give a fingerprint of the oil and high-resolution GC with a capillary column on the material boiling below 343°C. The high-resolution method allows the determination of the ratio of pristane to phytane, which is characteristic for many oils (Figures 8 and 9). Further tentative identification may be made by employing a flame photometric sulfur detector to give a sulfur fingerprint of the oil. This method is especially useful for biodegraded samples, which may give an unrecognizable FID hydrocarbon fingerprint but still give a characteristic sulfur fingerprint since the sulfur-containing compounds in the oil are more resistant to biodegradation than many of the hydrocarbons. In its ultimate form this type of identification is carried out by GC–high-resolution mass spectrometry, when it is possible to identify crude oils from closely related sources by measuring the ratios of individual benzothiophenes and dibenzothiophenes.

It should be noted that all the methods identify the original geographical and geological source of the oil and not necessarily the immediate source such as a particular ship or storage tank. This requires confirmatory circumstantial evidence and the availability of a valid reference sample.

**Figure 8** Chromatogram of <343°C fraction of Sarir crude oil. (From IP 318/75, courtesy of the Institute of Petroleum.)

**Figure 9** Chromatogram of <343°C fraction of Light Nigerian crude oil. (From IP 318/75, courtesy of the Institute of Petroleum.)

Another, as yet unsolved, problem is how to pinpoint the time of a particular spill, since the effects of weathering are extremely variable and depend on the microclimatic conditions to which a sample has been subjected. The use of two radioactive isotopes of iodine in known ratios to label cargoes has been proposed to resolve this problem, but this solution, although elegant from a purely scientific point of view, is as bad, environmentally, as the original problem and the method has never been adopted on a large scale.

## Plant Control

GC can be used to give automatic feedback control of plant and operating systems such as pipelines but is less frequently used on a direct basis than might be expected. Most plant control by GC is effected by

manually transporting a sample from the plant to a standard laboratory instrument housed in a safe area within the refinery. The main reason is that it takes a considerable time for any altered conditions such as temperature to have an effect on large plants. The second reason, which follows from the first, is that if rapid analysis near the plant is unnecessary then there is little point in using a plant instrument and exposing it to a hostile environment. Another factor is the difficulty of sampling on a continuous basis directly from a plant stream. It is extremely difficult to ensure a completely clean sample and the presence of a small rust particle is sufficient to destroy the highly polished surfaces of liquid sampling valves. Fluid logic devices have been employed experimentally to overcome this problem but they do not seem to have achieved wide acceptance.

## Other Techniques

The methods outlined above are just a few of the analyses carried out by GC in the petroleum industry. No examples of the use of headspace GC, or GC coupled to other chromatographic methods such as thin-layer chromatography or LC, have been given. GC coupled to mass spectrometry, which has been briefly mentioned, is probably the most important technique

available today for the qualitative analysis of petroleum mixtures and has been applied to topics ranging from organic geochemistry to occupational hygiene.

## Chiral Separations

**V Schurig**, Institute für Organische Chemie der Universität, Tübingen, Germany

© 2005, Elsevier Ltd. All Rights Reserved.

This article is reproduced from the first edition, pp. 1851–1860, © 1995, Elsevier Ltd., with revisions made by the Editor.

The unambiguous determination of enantiomeric compositions and absolute configurations is an important analytical task in the synthesis, characterization, and use of nonracemic compounds (optical isomers, enantiomers) such as chiral research chemicals, auxiliaries, drugs, pesticides, herbicides, pheromones, flavors, and fragrance. As the insight into chirality–activity relationships steadily improve and, as a consequence, legislation concerning chiral compounds becomes more and more stringent, the development of precise methods for the determination of enantiomeric purities up to, and in some cases higher than, ee = 99% is of great importance (ee, enantiomeric excess, is the percentage by which one enantiomer, *R*, is in excess in the (racemic) mixture of *R* and *S*: %ee = 100(*R* – *S*)/(*R* + *S*)).

The difficulty in determining ee arises from the fact that enantiomers have (apart from their chiroptical properties) *identical* properties in an *achiral* environment (assuming ideal conditions). Methods of distinguishing enantiomers must, therefore, rely on their chiroptical properties (polarimetry, circular dichroism, optical rotary dispersion) or must employ a *chiral* auxiliary in the spirit of Pasteur's resolution principles via diastereomer formation or interaction (e.g., in nuclear magnetic resonance (NMR) spectroscopy or chromatography). Because of high efficiency, sensitivity, and speed, chiral separation by gas chromatography represents a highly versatile technique for enantiomer analysis in the entire range of enantiomeric excess. Yet the prerequisite of the method is the volatility, thermal stability, and resolvability of the chiral analyte, which restricts its general use.

The separation of enantiomers by gas chromatography (GC) can be performed in two modes.

(a) *Indirect method*. Off-column conversion of enantiomers into diastereomeric derivatives by chemical

reaction with an *enantiomerically pure* chiral auxiliary and subsequent gas chromatographic separation of the diastereomers on a conventional *achiral* stationary phase.

(b) *Direct method*. Gas chromatographic separation of the enantiomers on a *chiral* stationary phase containing an auxiliary resolving agent of high (but not necessarily complete) enantiomeric purity.

While method (a) involves the formation of *diastereomers* before separation, method (b) involves the rapid and reversible *diastereomeric interaction* between the nonracemic stationary phase (selector) and the racemic (or enriched) analyte (selectand). The conversion of enantiomers into diastereomers and the subsequent chromatographic analysis of the diastereomeric ratio by method (a) requires the following conditions:

- The analyte must contain a suitable reactive group (preferably only one functionality in close proximity to the chiral center) undergoing a quantitative transformation with the chiral auxiliary compound with little formation of side-products.
- No kinetic resolution must result from the transformation of the mixture of enantiomers into diastereomers. The reaction should ideally therefore go to completion.
- There must be no racemization of either the analyte or of the auxiliary compound in the reaction that transforms the mixture of enantiomers into diastereomers.
- The auxiliary reagent must be enantiomerically pure for the sake of convenient and accurate analysis. Otherwise, an error is introduced in the determination of enantiomeric excess which, however, can be corrected for to a first approximation if the ee of the auxiliary is known.
- There must be no accidental change in the ratio of the diastereomers formed during sample manipulations. Since diastereomers display different physical properties, fractionation by incomplete recovery, decomposition, and losses may occur during work-up, isolation, and sample handling. In chromatography, fractionation may occur in split injection techniques and the original enantiomeric composition may be seriously falsified by differing detector responses to diastereomers.

Consequently, method (b) is preferred whenever possible for the determination of enantiomeric excess because it lacks the above drawbacks. This approach requires an efficient selector–selectand system displaying chiral recognition. Fortunately, with

high-resolution capillary columns, efficiency is high enough to resolve racemates having a difference of free enthalpy (Gibbs free energy) of diastereomeric association as little as  $0.08 \text{ kJ mol}^{-1}$ . With method (b) no fractionation of the enantiomers is expected at any time during the analytical procedure (cf. sources of error, below) and enantiomeric excess determined for the analyte by method (b) is independent of the enantiomeric purity of the chiral stationary phase employed. A low enantiomeric purity of the chiral auxiliary, however, results in small separation factors  $\alpha = k_R/k_S$  ( $k$  = retention factor, formerly capacity factor). The success of a chiral separation can be verified by control experiments. Unequivocal criteria of enantiomer separation are the occurrence of *peak coalescence (first kind)* when a racemic stationary phase is used and of *peak inversion (first kind)* of clearly resolved peaks of an enriched analyte when stationary phases of opposite configuration are applied. Method (b) is especially useful for determination of enantiomeric excess when no sample derivatization is required, e.g. in headspace analysis where the volatile enantiomers can be analysed directly, in the absence of enantioselective associations in the liquid phase, with minute amounts of gas. Owing to the enormous separating power of gas chromatography, notably in the high-resolution capillary column mode of operation, contaminants and impurities are separated from the sample and the simultaneous analysis of the enantiomers of different compounds (e.g., all amino acids) is feasible in one analytical run. Moreover, established ancillary techniques such as multidimensional chromatography (multiple-column operation), use of interfacing and coupling methods (GC–mass spectrometry (MS)) can also readily be adapted in chiral separations. Detection limits can be extended down to the picogram level by GC–MS or GC electron capture detection. GC–MS selected-ion monitoring (SIM) can detect enantiomers in complex matrices.

In gas chromatographic chiral separation, useful information may be obtained from the peak parameters depicted in Table 1. Enantioselectivity  $-\Delta_{R,S}(\Delta G^\circ)$  (cf. (2) in Table 1) arises from the diastereomeric interaction between the enantiomers of the selectand and the selector. Assuming a fast and reversible equilibration, enantiomer separation by gas chromatography is governed by thermodynamics according to the Gibbs–Helmholtz equation (the subscripts refer to enantiomers  $R$  and  $S$ ):

$$\begin{aligned} RT \ln(K_R/K_S) &= -\Delta_{R,S}(\Delta G^\circ) \\ &= -\Delta_{R,S}(\Delta H^\circ) + T\Delta_{R,S}(\Delta S^\circ) \quad [1] \end{aligned}$$

**Table 1** Enantiomeric peak parameters and derived properties

Peak parameter	Derived property	Expression
Peak retention	Chemoselectivity <sup>a</sup>	$K, -\Delta G^\circ$
Peak separation	Enantioselectivity	$-\Delta_{R,S}(\Delta G^\circ) = RT \ln \alpha^b$
Peak coalescence (third kind)	Enantiomerization barrier	$\Delta G^\ddagger$
Peak ratio	Enantiomer ratio	ee
Peak assignment	Enantiomer configuration	$R$ or $S$

<sup>a</sup> Involving dilute metal coordination compounds permitting the measurement of association constants from retention data.

<sup>b</sup> If the stationary phase is a binary system with an achiral solvent the chiral separation factor  $\alpha = k_R/k_S$  ( $k$ =retention factor) also includes retention on the achiral component.

From Schurig V and Bürkle W (1982) Extending the scope of enantiomer resolution by complexation gas chromatography. *Journal of the American Chemical Society* 104: 7573–7580.

For an association or coordination process, the quantities  $\Delta_{R,S}(\Delta S^\circ)$  and  $-\Delta_{R,S}(\Delta H^\circ)$  usually have opposite signs, thus having opposing effects in determining  $-\Delta_{R,S}(\Delta G^\circ)$ . When  $\Delta_{R,S}(\Delta G^\circ) = 0$  ( $K_R = K_S$ ; no enantiomer separation), the *isoenantioselective* temperature  $T_{\text{isoenant}}$

$$T_{\text{isoenant}} = \Delta_{R,S}(\Delta H^\circ) / \Delta_{R,S}(\Delta S^\circ) \quad [2]$$

is reached, where *peak coalescence (second kind)* occurs. At  $T_{\text{isoenant}}$  the sign of enantioselectivity changes (*peak inversion (second kind)*). Below the coalescence temperature, the sign of enantioselectivity  $\Delta_{R,S}(\Delta G^\circ)$  is governed by  $-\Delta_{R,S}(\Delta H^\circ)$ , and above it by  $\Delta_{R,S}(\Delta S^\circ)$ . Evidence for the reversal of enantioselectivity has indeed been found in gas chromatographic enantiomer separation. In practice, gas chromatography can rarely be carried out at or above  $T_{\text{isoenant}}$ ; hence, in general, enantioselectivity is enthalpy-controlled and separation factors  $\alpha$  increase with decreasing temperature.

The configurational integrity of the enantiomers during the gas chromatographic process of separation is essential to the correct enantiomer analysis. When enantiomers are labile to inversion of configuration, characteristic peak profiles are obtained that are recognized by the appearance of a plateau between the terminal peaks of the enantiomers. Using peak form analysis, activation parameters of enantiomerization ( $\Delta G^\ddagger$ ) (cf. (3) in Table 1) can be determined by *dynamic* gas chromatography. If enantiomerization is fast within the chromatographic timescale, *peak coalescence (third kind)* will arise.

Because an (achiral) detection device will respond equally to enantiomers irrespective of their molecular configuration, the comparison of relative peak areas provides an unambiguous measure of the enantiomeric ratio from which enantiomeric excess can be

calculated, provided the detector response is strictly linear.

The assignment of absolute configurations is another important application in enantiomer analysis. Unequivocal proof of absolute configuration can be obtained by coinjection of a sample with established stereochemistry. The correlation of absolute configuration with the elution order of structurally related enantiomers, e.g., members of homologous series of compounds, may lead to serious pitfalls, since many causes of peak inversions are feasible.

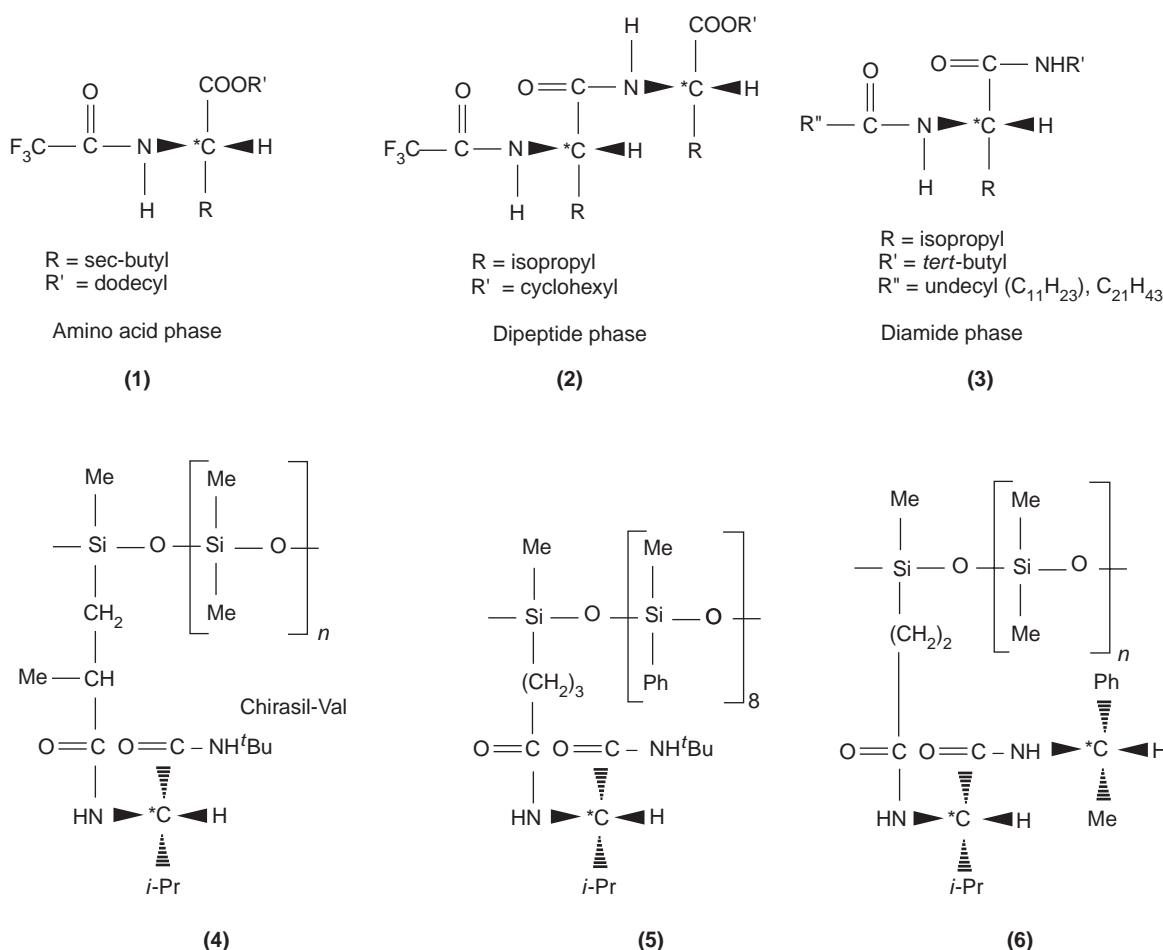

## Classification of Chiral Stationary Phases

The classification of the principal chiral stationary phases for gas chromatography in its historical context is depicted in Table 2.

Enantiomer separation by gas chromatography has essentially been carried out by three principal methods:

- separation on nonracemic amino acid derivatives via hydrogen bonding;
- separation on nonracemic metal coordination compounds via complexation; and
- separation on cyclodextrin derivatives via (*inter alia*) inclusion

Initially, all selectors were used as involatile liquids or as solutions in squalane or polysiloxane. Later, the selectors were chemically linked to polysiloxanes (Chirasil type stationary phases). This strategy was first exemplified by the synthesis of Chirasil-Val (Scheme 1). This approach has recently been extended

Scheme 1

to complexation gas chromatography by the synthesis of Chirasil-Metal and to inclusion gas chromatography by the synthesis of Chirasil-Dex. The chemically bonded chiral polymers combine the chemical affinity of the selector with the unique coating properties and thermal stability of polysiloxanes, affording capillary columns with high efficiency and extended range of operating temperatures. Moreover, Chirasil stationary phases can be cross-linked and immobilized on the inner wall of fused-silica capillary columns. Immobilization of Chirasil stationary phases is a prerequisite for their use in chiral supercritical fluid chromatography (SFC) and electrochromatography for enantiomer analysis of involatile and thermally labile racemates.

### Chiral Gas Chromatography Using Nonracemic Amino Acid Derivatives

The first successful separation of racemic *N*-trifluoroacetyl amino acid esters on glass capillary columns

coated with *N*-trifluoroacetyl-L-isoleucine lauryl ester ((1), **Scheme 1**) was achieved by Gil-Av, Feibush, and Charles-Sigler in 1966, and the great potential of this fundamental approach was clearly demonstrated. A number of improved hydrogen-bonding chiral phases were investigated subsequently, such as the dipeptide phase (2). It was recognized that the C-terminal amino acid was not essential to chiral recognition, while the additional amide function proved important for hydrogen bonding. Therefore, the second chiral center was removed by preparing the diamide phase (3), e.g., derived from valine. This selector was subsequently coupled by Frank, Nicholson and Bayer via the amino function to a statistical copolymer of dimethylsiloxane and (2-carboxypropyl)methylsiloxane of appropriate viscosity to yield Chirasil-Val (4). Chirasil-Val exhibits excellent efficiencies for the enantiomer separation of a variety of classes of compounds prone to hydrogen bonding over a broad temperature range. Chirasil-Val is commercially available in both enantiomeric forms. The simultaneous enantiomer separation of all proteinogenic

**Figure 1** Simultaneous enantiomer separation of 20 amino acids as *N,O,S*-pentafluoropropanoate isopropyl ester (histidine as *N*<sup>im</sup>-ethoxycarbonyl) derivatives by gas chromatography on Chirasil-Val [IV] between 85 and 185 °C at 0.35 bar (gauge) hydrogen. Column: 50 m × 0.27 mm (i.d.) glass capillary. D-enantiomers are eluted before L-enantiomers. (From Bayer E (1983) *Chirale Erkennung von Naturstoffen an optisch aktiven Polysiloxanen*. *Zeitschrift für Naturforschung* 38b: 1281–1291.)

**Scheme 2**

amino acids in less than 25 minutes is illustrated in Figure 1.

Another direct approach to chiral polymeric stationary phases is the modification of commercially available polysiloxanes containing reactive side-groups. Thus, the diamide phase (3) was linked to a modified XE-60 polysiloxane to give (5) and (6). In (6) another center of chirality (*R*- or *S*-configuration) has been introduced in the amide group (XE-60-L-Val-(*R* or *S*)- $\alpha$ -pea) by König *et al.*

Enantiomer separation by hydrogen-bonding stationary phases generally requires substrate derivatization.

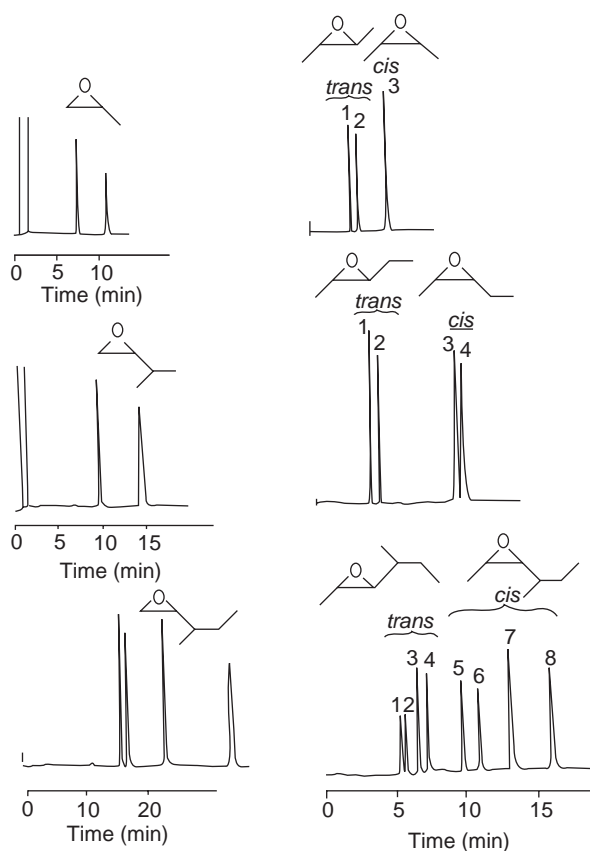

## Chiral Gas Chromatography Using Nonracemic Metal Coordination Compounds

Coordination interactions represent another strategy for producing chiral recognition in gas chromatography. Thus, the chiral metal coordination compound dicarbonylrhodium(I)-3-trifluoroacetyl-(1*R*)-campho-

rate ((7), Scheme 2) was employed to separate racemic 3-methylcyclopentene. The scope of enantiomer separation by complexation gas chromatography was later extended to oxygen-, nitrogen-, and sulfur-functionalized racemates using nonracemic ketoenolate *bis* chelates of divalent transition metal ions derived from terpene ketones such as camphor, menthone, carvone, and pulegone. Thus, manganese(II)-, and nickel(II)-[3-(heptafluorobutanoyl)-(1*R*)-camphorate] (8), (9) proved to be versatile stationary phases for the separation of underivatized cyclic ethers, esters, acetals, aldehydes, ketones, and alcohols. In Figure 2 the enantiomer separation of oxiranes by complexation gas chromatography is illustrated.

A limiting factor of Chirametal stationary phases is the low temperature range (25–120 °C). Improved thermo-stable polymeric stationary phases (Chirasil-Metal) (10) have also been prepared. Figure 3 shows the enantiomer separation of cyclic ethers in less than 20 s.

The immobilized Chirasil-Metal stationary phase can also be used in supercritical fluid chromatography

**Figure 2** Enantiomer separation of aliphatic oxiranes by complexation gas chromatography on nickel(II) bis[3-(heptafluorobutanoyl)-(1*S*)-19-ethylidene-camphorate] ( $0.125 \text{ mol kg}^{-1}$  in OV-101) between 70°C and 90°C. Column:  $25 \text{ m} \times 0.25 \text{ mm}$  (i.d.) glass capillary. (From Schurig V and Betschinger F (1992) Metal-mediated enantioselective access to unfunctionalized aliphatic oxiranes: prochiral and chiral recognition. *Chemical Reviews* 92: 873–888.)

(SFC) with supercritical carbon dioxide as mobile phase.

## Chiral Gas Chromatography Using Cyclodextrin Derivatives

The first gas chromatographic enantiomer separation on a cyclodextrin-based stationary phase was that of the apolar racemic hydrocarbons  $\alpha$ - and  $\beta$ -pinene and *cis*- and *trans*-pinane on *packed* columns coated with native  $\alpha$ -cyclodextrin dissolved in formamide. Very soon it was recognized that alkylated cyclodextrins could be employed in capillary columns for high-resolution enantiomer analysis. Thus, molten permethylated  $\beta$ -cyclodextrin ( $\beta$ -CD, heptakis (2,3,6-tri-*O*-methyl)- $\beta$ -cyclodextrin) (11) was used at temperatures above 100°C. Permethylated  $\beta$ -cyclodextrin (11) has also been used by Schurig

**Figure 3** Enantiomer separation of 2-methyltetrahydrofuran and 2-methyloxetane by complexation gas chromatography on immobilized Chirasil-Nickel (10) at 115°C and 2.0 bar (gauge) nitrogen (left) and 140°C and 2.0 bar (gauge) nitrogen (right). Column:  $1.5 \times 0.05 \text{ mm}$  (i.d.) fused-silica capillary. (From Schurig V, Schmalzing D, and Schleimer M (1991) Enantiomeric separation on immobilized Chirasil-Metal and Chirasil-Dex by gas chromatography and supercritical fluid chromatography. *Angewandte Chemie, International Edition* 30: 987–989.)

and Nowotny as a solution in moderately polar polysiloxanes (e.g., OV-1701). By diluting the chiral selector, the inherent enantioselectivity of cyclodextrins is combined with the unique chromatographic properties of polysiloxanes. Fused-silica capillary columns coated with (11) in OV-1701 are commercially available and show very broad applicability in enantiomer separation of various classes of compounds. The resolution of racemic unfunctionalized saturated hydrocarbons is illustrated in **Figure 4**.

A chiral test mixture has been devised to probe the efficiency and performance of permethylated  $\beta$ -cyclodextrin/OV-1701 capillary columns. This so-called *Schurig test mixture* contains both highly polar racemates (a free acid, a free base, a diol, an alcohol, and an amine) and apolar racemates (hydrocarbons), as shown in **Figure 5**.

Chemically linking the cyclodextrin derivatives to the polysiloxane backbone affording Chirasil-Dex (12)

**Figure 4** Enantiomer separation of *trans*- and *cis*-1-ethyl-2-methylcyclohexane and of *trans*- and *cis*-1-methyl-2-*n*-propylcyclohexane by gas chromatography on heptakis(2,3,6-tri-*O*-methyl)- $\beta$ -cyclodextrin (11) (10%, 0.08 mol kg<sup>-1</sup> in OV 1701) at 50 °C and 0.7 bar (gauge) helium. Column: 25 m  $\times$  0.25 mm (i.d.) fused-silica capillary. (From Schurig V, Nowotny H-P, and Schmalzing D (1989) Gas-chromatographic enantiomer separation of unfunctionalized cycloalkanes on permethylated  $\beta$ -cyclodextrin. *Angewandte Chemie, International Edition* 28: 736–737.)

proved to be a useful extension of this approach. The immobilization of the resulting Chirasil-Dex stationary phases on the fused-silica surface by thermal treatment represents another refinement of the methodology. Immobilized Chirasil-Dex phases are quite resistant to stationary-phase bleeding, they are compatible with solvent intake and are insensitive to temperature shock, and have an extended working temperature range (–10 °C to 250 °C). The immobilization of Chirasil-Dex (19) was the prerequisite for enantiomer separation of involatile racemates by SFC.

Per-*n*-pentylated and 3-acyl-2,6-*n*-pentylated cyclodextrins are viscous liquids even below room temperature. The cyclodextrin derivatives (13)–(18) (Lipodex) (Scheme 3) have been used in the *undiluted* form for the separation of enantiomers of many classes of compounds on deactivated glass capillary

**Figure 5** Enantiomer separation of  $\alpha$ -pinene (1,2), *trans*-pinene (3,4), *cis*-pinene (5,6), 2,3-butanediol (rac) (7,8), 2,3-butanediol (meso) (9),  $\gamma$ -valerolactone (10,11), 1-phenylethylamine (12,13), 1-phenylethanol (14,15), and 2-ethylhexanoic acid (16,17) (Schurig test mixture) by gas chromatography on heptakis (2,3,6-tri-*O*-methyl)- $\beta$ -cyclodextrin (10%, 0.08 mol kg<sup>-1</sup> in OV 1701) at 50 °C and 0.7 bar (gauge) helium. Column: 50 m  $\times$  0.25 mm (i.d.) fused-silica capillary. (Chrompack International, Middelburg, The Netherlands.)

columns by König *et al.* Addition of polysiloxanes also allows the efficient coating of fused-silica columns that are commercially available. The more polar cyclodextrin derivatives containing hydroxypropyl, free hydroxy groups or trifluoroacetyl groups, (19)–(23) were coated on nondeactivated fused-silica capillary columns by Armstrong *et al.*

The 6-*O*-*tert*-butyldimethylsilyl (TBDMS)-protected cyclodextrin derivatives (24) and (25) employed by Mosandl *et al.* proved to be versatile selectors for enantiomer separation by gas chromatography.

In Figures 6 and 7 representative gas chromatograms employing different cyclodextrin derivatives are shown. The presence of three hydroxyl groups of different reactivities offers an enormous number of possible cyclodextrin ( $\alpha$ ,  $\beta$ ,  $\gamma$ ) derivatives. As yet, no universally applicable cyclodextrin phase is available and selection is still a matter of trial and error. Separation factors  $\alpha$  for enantiomers are generally low. This feature is compensated by the high efficiency of capillary columns. Of disadvantage is the fact that cyclodextrins are available only in the all-*D* form. Hence, peak switching in the analysis of enantiomeric impurities eluted as the second peak, and therefore difficult to detect, is not possible with cyclodextrin stationary phases.

## Applications

Enantioselective gas chromatography is applied for enantiomeric analysis in many different fields such as

**Scheme 3** Cyclodextrin-derived stationary phases. **Lipodex-stationary phases.** Hexakis(2,3,6-tri-*O*-*n*-pentyl)- $\alpha$ -cyclodextrin (**13**). Hexakis(3-*O*-acetyl-2,6-di-*O*-*n*-pentyl)- $\alpha$ -cyclodextrin (**14**). Heptakis(2,3,6-tri-*O*-*n*-pentyl)- $\beta$ -cyclodextrin (**15**). Heptakis(3-*O*-acetyl-2,6-di-*O*-*n*-pentyl)- $\beta$ -cyclodextrin (**16**). Octakis(2,3,6-tri-*O*-*n*-pentyl)- $\gamma$ -cyclodextrin (**17**). Octakis(3-*O*-butanoyl-2,6-di-*O*-*n*-pentyl)- $\gamma$ -cyclodextrin (**18**). **Polar cyclodextrin stationary phases.** (*O*-(*S*)-2-hydroxypropyl)-per-*O*-methyl)- $\alpha$ -cyclodextrin (PMHP- $\alpha$ -CD) (**19**). (*O*-(*S*)-2-hydroxypropyl)-per-*O*-methyl)- $\beta$ -cyclodextrin (PMHP- $\beta$ -CD) (**20**). Hexakis(2,6-di-*O*-*n*-pentyl)- $\alpha$ -cyclodextrin (dipentyl- $\alpha$ -CD) (**21**). Heptakis(2,6-di-*O*-*n*-pentyl)- $\beta$ -cyclodextrin (dipentyl- $\beta$ -CD) (**22**). Heptakis(3-*O*-trifluoroacetyl-2,6-di-*O*-*n*-pentyl)- $\beta$ -cyclodextrin (DPTFA- $\beta$ -CD) (**23**). **6-TBDMS-modified cyclodextrin stationary phases.** Heptakis(2,3-di-*O*-acetyl-6-*O*-*tert*-butyldimethylsilyl)- $\beta$ -cyclodextrin (**24**). Heptakis(2,3-di-*O*-methyl-6-*O*-*tert*-butyldimethylsilyl)- $\beta$ -cyclodextrin (**25**).

authenticity control of essential oils, flavors, and fragrances, in clinical chemistry, in the characterization of chiral terpenes, pheromones and organochlorine pesticides, and in the search for extraterrestrial homochirality. Asymmetric and enzymatic reactions, kinetic resolutions require the correct determination of high ee values. Many hyphenated approaches in enantioselective gas chromatography are known such as GC–MS (SIM = selected ion monitoring), two-dimensional approaches GC–GC and LC–GC and GC–GC–MS (IR = isotopic ratio). Derivatized amino acid analysis is preferentially performed on Chirasil-Val stationary phases.

It is recommended to use short columns (2–5 m  $\times$  250  $\mu$ m) for the analysis of less volatile analytes. The loss of efficiency is usually outweighed by the increase of selectivity at reduced elution temperatures.

## Preparative Enantiomer Separations by Gas Chromatography

Preparative enantiomer separations are restricted to volatile racemic compounds. However, in contrast to liquid chromatography, the removal of the gaseous

mobile phase from volatiles is straightforward. In the development of enantioselective gas chromatography, packed columns containing chiral selectors coated on solid supports were initially involved (e.g., involatile amino acid derivatives, metal coordination compounds, and native cyclodextrins).

In complexation gas chromatography, semipreparative separations of spiroketals (among them pheromones) have been reported. The preparative invertomer separation of 1-chloro-2,2-dimethylaziridine permitted the determination of chiroptical data, absolute configuration and inversion barrier. Very large separation factors  $\alpha$  were observed for saturated hydrocarbons (*cis*- and *trans*-pinane, camphene) on a mixture of  $\alpha$ -cyclodextrin in formamide impregnated on celite. The preparative enantiomer separation of  $\alpha$ -ionone on (**18**) and of all-*trans*-perhydrotriphenylene on (**25**) has been described. The large separation factors observed for the inhalational anesthetics enflurane, isoflurane, and desflurane on (**18**) allowed their enantiomer separation for subsequent biomedical trials and acquisition of chiroptical data. The continuous preparative enantiomer separation of enflurane and

**Figure 6** Enantiomer separation of lactones by gas chromatography on octakis(3-*O*-butanoyl-2,6-di-*O*-*n*-pentyl)- $\gamma$ -cyclodextrin (**18**) (undiluted) at 150 °C and 1 bar (gage) hydrogen. Column: 50 m  $\times$  0.25 mm (i.d.) glass capillary. (From König WA, Krebber R, and Mischnick P (1989) Cyclodextrins as chiral stationary phases in capillary gas chromatography. *Journal of High Resolution Chromatography* 12: 732–738.)

isoflurane was also performed by an enantioselective gas-chromatographic simulated moving bed unit (enantioselective GC-SMB).

For semi-preparative separations in the 0.5–2 mg range analytical thick-film-wide-bore capillary columns coated with modified cyclodextrins can be used.

## Data Retrieval for Enantioselective Gas Chromatography

The Chirbase/GC and Chirbase/Flavor data banks document separations of enantiomers performed by gas chromatography. It contains bibliographical, structural, and chromatographic (separation factor  $\alpha$ , retention factor  $k$  and resolution  $R_s$ ) information based on standard database software.

**Figure 7** Enantiomer separation of methyl 2-chloropropanoate by gas chromatography on heptakis(3-*O*-trifluoroacetyl-2,6-di-*O*-*n*-pentyl)- $\beta$ -cyclodextrin (**23**) (undiluted) at three temperatures. Column: 20 m  $\times$  0.25 mm (i.d.) nondeactivated fused-silica capillary. (From Berthod A, Li W, and Armstrong DW (1992) Multiple enantioselective retention mechanisms on derivatized cyclodextrin gas chromatography chiral stationary phases. *Analytical Chemistry* 64: 873–879.)

Gastric juice is a composite secretion of the different cells that line the glands of the gastric mucosa of the stomach. It consists of parietal and nonparietal components. The parietal component includes hydrochloric acid (HCl) and intrinsic factor (IF). The nonparietal component, itself a composite alkaline secretion, includes mucus,  $\text{HCO}_3^-$ ,  $\text{Na}^+$ ,  $\text{Cl}^-$ ,  $\text{K}^+$ , and proteins that include the proteolytic enzymes pepsinogens I and II secreted by the chief cells. Despite knowledge of the composition of gastric juice and the availability of techniques to measure the various components, conventional gastric analysis as performed in man has involved mainly the measurement of gastric acid secretion. This is largely because the clinical significance of abnormal gastric acid secretion is well established and is also due in part to the fact that it is generally agreed that gastric acid secretion parallels pepsinogen and IF secretion in

infants, children, and adults in both the basal and stimulated states. It may also be partly because the determination of most of the other components of gastric juice is still restricted to research investigations with no proven clinical significance.

In clinical practice, gastric juice analysis is routinely used to assist in the diagnosis of diseases associated with hypersecretion, hyposecretion, or no secretion of acid. The major clinical indications for gastric juice analysis include (1) peptic ulcer patients not responding to medical treatment, (2) Zollinger-Ellison syndrome (ZES), (3) the evaluation of post-vagotomy patients to test completeness of vagotomy, and (4) the pre- and postoperative assessment of acid-reducing surgery in patients with peptic ulcers. Other clinical indications include atrophic gastritis, pernicious anaemia, Ménétrier's disease, and antral G-cell hyperplasia. In the laboratory, gastric juice analysis is used to monitor the onset, duration, and peak effect of drugs that inhibit gastric acid secretion, and consequently in the determination and scheduling of therapeutic dosage regimens. Also, gastric secretory tests are used in research for investigating the physiology and pathophysiology of gastric function.

This article is reproduced from the previous edition, pp. 1915–1924, © 1995, Elsevier Ltd., with an updated Further Reading list supplied by the Editor.

Gastric juice is a composite secretion of the different cells that line the glands of the gastric mucosa of the stomach. It consists of parietal and nonparietal components. The parietal component includes hydrochloric acid (HCl) and intrinsic factor (IF). The nonparietal component, itself a composite alkaline secretion, includes mucus,  $\text{HCO}_3^-$ ,  $\text{Na}^+$ ,  $\text{Cl}^-$ ,  $\text{K}^+$ , and proteins that include the proteolytic enzymes pepsinogens I and II secreted by the chief cells. Despite knowledge of the composition of gastric juice and the availability of techniques to measure the various components, conventional gastric analysis as performed in man has involved mainly the measurement of gastric acid secretion. This is largely because the clinical significance of abnormal gastric acid secretion is well established and is also due in part to the fact that it is generally agreed that gastric acid secretion parallels pepsinogen and IF secretion in

infants, children, and adults in both the basal and stimulated states. It may also be partly because the determination of most of the other components of gastric juice is still restricted to research investigations with no proven clinical significance.

In clinical practice, gastric juice analysis is routinely used to assist in the diagnosis of diseases associated with hypersecretion, hyposecretion, or no secretion of acid. The major clinical indications for gastric juice analysis include (1) peptic ulcer patients not responding to medical treatment, (2) Zollinger-Ellison syndrome (ZES), (3) the evaluation of post-vagotomy patients to test completeness of vagotomy, and (4) the pre- and postoperative assessment of acid-reducing surgery in patients with peptic ulcers. Other clinical indications include atrophic gastritis, pernicious anaemia, Ménétrier's disease, and antral G-cell hyperplasia. In the laboratory, gastric juice analysis is used to monitor the onset, duration, and peak effect of drugs that inhibit gastric acid secretion, and consequently in the determination and scheduling of therapeutic dosage regimens. Also, gastric secretory tests are used in research for investigating the physiology and pathophysiology of gastric function.

This article gives an overview of the indications, method of sampling, and the methods and techniques used for the analyses of the various constituents of gastric juice; the interpretations and clinical importance of the results with particular emphasis on acid secretion are also discussed. The methods are limited to those employed in man but relevant techniques and results obtained in animal studies are mentioned.

## Sampling of Gastric Juice

### Nasogastric Intubation

Samples of gastric juice for analyses are obtained through nasogastric intubation into the most dependent part of the stomach, the antrum. The tube should be stiff to avoid bending or coiling, its walls strong enough to prevent collapse during suction and preferably plastic, which is less irritating than rubber. Double-lumen nasogastric tubes with the tips of the main and smaller tubes in the gastric antrum and upper body, respectively, are preferable. The smaller tube is used for the infusion of nonabsorbable markers. A variety of nasogastric tubes are available commercially, although it is common practice among investigators to have them custom made; generally, sump tubes are the most popular. The side holes should be made close to the tip of the tube to ensure a localized aspiration of gastric juice. Confirmation of accurate nasogastric tube placement in the stomach is extremely important because tubes may pass into the duodenum or coil in the stomach or oesophagus. Nasogastric tube placement is most accurately performed under fluoroscopic guidance. Nevertheless, nonradiologic methods of confirming 'blind' tube placement are also in use and include the water recovery test, epigastric auscultation of insufflated air, measurement of the pH of aspirated fluid, and passing the nasogastric tube so that its tip is 550–600 mm beyond the nares. The water recovery test has been shown in several studies to be as accurate as fluoroscopy in nasogastric tube placements; hence it is the most widely used nonradiologic method. It involves drinking 20 ml of water after the nasogastric tube is passed into the stomach and attempting immediate syringe aspiration through the tube. The tube is then withdrawn 25 mm at a time and the test repeated until the shortest distance of the tube where 90% or more (18–20 ml) of the amount of water drunk was recovered, which signifies a 'pass'. In patients with previous gastric resection or drainage operations, fluoroscopically guided tube placement is indicated to ensure the most optimal position.

### Collection

With the patient sitting or lying in the left lateral decubitus position, the throat is sprayed with a local anesthetic to reduce any discomfort and the tube is passed into the gastric antrum under fluoroscopic guidance. Gastric juice is aspirated by constant hand or continuous mechanical suction and put into separate, consecutive 10- or 15-min sample bottles. It is recommended that the suction be stopped periodically when using either method to prevent blockage of the side holes of the nasogastric tube by mucus, mucosa, or food. Accessory small air bleed tubes can also be attached to the nasogastric tube to prevent blockage.

### Nonabsorbable Volume Markers

In the presence of an accurate nasogastric tube placement, most studies using nonabsorbable volume markers have reported about a 90% recovery, indicating that an inevitable loss of about 10% of the gastric juice volume occurs through the pylorus. The infusion of nonabsorbable volume markers is used to improve the accuracy of the recovered gastric volumes. Table 1 summarizes marker substances that have been used and those that have potential for human use and their methods of estimation. Of these markers, poly(ethylene glycol) (PEG) has been the most widely used. However, the methods used for its estimation are still laborious, nonspecific, insensitive, and are associated with analytical errors. In addition,

**Table 1** Summary of nonabsorbable gastric volume markers and their methods of analysis

Markers	Methods of estimation
Poly(ethylene glycol) (PEG)	Turbidimetric analysis
<sup>14</sup> C-PEG	Liquid scintillation counting
<sup>3</sup> H-PEG	Liquid scintillation counting
<sup>a</sup> Radioiodinated ( <sup>131</sup> I-) serum albumin	Scintillation counting
Phenol red	<sup>b</sup> Spectrophotometry
<sup>51</sup> Chromium chloride ( <sup>51</sup> CrCl <sub>3</sub> )	Scintillation counting
<sup>51</sup> Cr-EDTA	Scintillation counting
<sup>c</sup> Cobalt-EDTA (Co-EDTA)	<sup>d</sup> Atomic absorption spectrometry Instrumental neutron activation analysis
<sup>c</sup> Chromium-EDTA (Cr-EDTA)	<sup>d</sup> Atomic absorption spectrometry Instrumental neutron activation analysis

<sup>a</sup>No longer in general use.

<sup>b</sup>Spectrophotometry is performed at 560 nm.

<sup>c</sup>Used so far in animals. Potential for routine use in human subjects.

<sup>d</sup>Cheaper, easier to use, and more readily available.

there is the risk of radioactive contamination associated with the use of  $^{14}\text{C}$ -PEG. Recently, in animals, nonradioactive cobalt-EDTA and chromium-EDTA have been introduced as gastrointestinal tract liquid-phase markers and have more accurate, sensitive, and specific methods of estimation, thus obviating the problems associated with the use of radioactive markers. Preliminary validation studies show good and comparable gastrointestinal recovery rates for both markers in animals and, therefore, great potential for human application. Gastric volume corrected for pyloric losses can be calculated from the following equation:

$$\frac{\text{Corrected gastric volume (ml)}}{\text{Recovered volume (ml)}} = \frac{\text{Recovered volume (ml)} \times [\text{Marker}] \text{ in instilled solution}}{[\text{Marker}] \text{ in recovered volume}}$$

where [Marker] is the concentration of marker.

## Methods and Techniques

The subject is intubated with a nasogastric tube after an 8–12 h overnight fast, usually, early in the morning. In patients with gastric outlet obstruction or decreased gastric motility, a clear liquid diet should be advised for at least 1 day prior to the study. Also, acid inhibitory drug treatment should be stopped 24 h before the commencement of a study or 48 h in the case of subjects on  $\text{H}^+/\text{K}^+$  ATPase inhibitors. Acid output in millimoles (mmol) is the product of the volume secreted in milliliters (ml) and the  $\text{H}^+$  concentration in millimoles per milliliter ( $\text{mmol ml}^{-1}$ ). The secretion of gastric acid is measured over a period of time, usually an hour, and is expressed as the acid output per hour ( $\text{mmol h}^{-1}$ ). Furthermore, acid output is measured in the resting basal state and during stimulation of acid secretion by pharmacologic agents and/or food. The results are reported respectively as the basal acid output (BAO), maximal acid output (MAO), and the peak acid output (PAO).

### Measurement of Gastric Acid Secretion

**Gastric aspiration** Simple aspiration of gastric juice through a nasogastric tube is the most widely used method of measuring gastric acid secretion in humans. Aspiration of gastric juice can also be performed during fiberoptic gastroscopy. The residual gastric contents are aspirated. The residual gastric juice sample and the samples of gastric juice aspirated thereafter, during the specific tests of acid secretion, should have the following gross

observation and analytic measurements performed on them: color, volume, pH,  $\text{H}^+$  concentration, and acid output.

Blood-staining or ‘coffee ground’ gastric juice indicates bleeding which could arise from the stomach, lower oesophagus, or duodenum. Bile-staining of gastric juice indicates duodenogastric reflux. In both these cases, the study should be repeated the next day and the cause of the bleeding should be sought. In subjects with previous gastric resection, it may be impossible to obtain bile-free samples.

The pH of an aliquot of the gastric aspirate is measured to the nearest 0.01 pH unit by using a glass electrode and pH meter. It is vital to accurately calibrate the glass electrode with standard buffer solutions of pH 1.09, 4.01, and 7.0 before and halfway through each batch of hourly samples of gastric juice. Gastric juice pH that stays above 6.0 after stimulation is defined as achlorhydria.

Hydrogen ion concentration in the aspirate can be determined either from the pH obtained by the glass pH electrode or by determining the titratable acidity. According to the method of Moore and Scarlata, the pH values determined by the glass pH electrode represent the negative logarithm of the hydrogen ion activity  $a_{\text{H}^+}$ . The hydrogen ion concentration ( $C_{\text{H}^+}$ ) is then calculated from the equation  $C_{\text{H}^+} = a_{\text{H}^+}/\gamma_{\text{H}^+}$ , where  $\gamma_{\text{H}^+}$ , a correction factor, is the activity coefficient of hydrogen ion in gastric juice which is assumed to be equal to the hydrochloric acid activity,  $\gamma_{\text{HCl}}$ , since it is not possible to determine the former for a single ion species. Tables of activity coefficients for determining hydrogen ion concentration at different concentrations of  $\text{Na}^+$  and  $\text{K}^+$  in gastric juice have been published.

Titratable acidity is determined by titration of aliquots of the gastric juice sample with  $0.1 \text{ mol l}^{-1}$  NaOH to neutrality. Although neutrality has been traditionally set at pH 7.0, the physicochemical point of neutrality, others have recommended titration to pH 7.4, the pH of plasma. This issue remains unsettled. The amount of NaOH (in  $\text{mmol l}^{-1}$ ) used for titration to neutrality (pH 7.0) is the titratable acidity.

Measurements of gastric acid secretion performed by gastric aspiration include basal, maximal, and peak acid output. Acid output cannot be accurately measured by gastric aspiration in the presence of food in the stomach; hence, it is not used to measure meal-stimulated acid output.

**Basal acid output (BAO)** An estimate of the resting, unstimulated acid secretion is defined as the sum of the acid output from the gastric aspirate obtained over four consecutive 15-min periods. Table 2 shows

**Table 2** Upper and lower limits of normal acid outputs in healthy adult men and women<sup>a</sup>

	Sex	Lower limit	Upper limit
BAO (mmol h <sup>-1</sup> )	Men	–	10.5
	Women	–	5.6
MAO (mmol h <sup>-1</sup> )	Men	6.9	47.8
	Women	5.0	30.2
PAO (mmol h <sup>-1</sup> )	Men	11.6	60.6
	Women	8.0	40.1
BAO/PAO ratio	Men	–	0.29
	Women	–	0.23

<sup>a</sup>Upper and lower limits of normal (95% confidence limits) were derived from data obtained from 100 healthy men and 50 healthy women. There were no lower limits of normal for BAO or for the ratio of BAO to PAO because many normal subjects have a BAO of zero. BAO, basal acid output; MAO, maximal acid output; PAO, peak acid output. (Reprinted with permission from Feldman M (1989) Gastric secretion in health and disease. In: Sleisenger MH and Fordtran JS (eds.) *Gastrointestinal Disease: Pathophysiology, Diagnosis, Management*, vol. I, pp. 713–734. Philadelphia: W.B. Saunders Company.)

the normal range of basal acid outputs for healthy adult men and women. For unknown reasons, normal BAO is higher in men than in women. The emotional state of the individual affects BAO. Repeated measurements of BAO in the same individual show a coefficient of variation of about 50% and vary from hour to hour in a circadian pattern.

**Maximal acid output (MAO) and peak acid output (PAO)** After measuring the BAO, the maximal acid secretory capacity expressed as the MAO and PAO are determined. A supra-physiological one-time dose of pentagastrin is administered subcutaneously (6 µg kg<sup>-1</sup>), intramuscularly (6 µg kg<sup>-1</sup>), or by continuous intravenous infusion (6 µg kg<sup>-1</sup> h<sup>-1</sup>). Histamine or the synthetic histamine analog, beta-zole, can also be used. The gastric contents are aspirated every 15-min period for 1 h and analyzed. The PAO is calculated by multiplying the sum of the two highest 15-min acid outputs by 2 and is expressed in mmol h<sup>-1</sup>. The MAO, also in mmol h<sup>-1</sup>, is the sum of the acid output of the four consecutive 15-min periods. The normal values of PAO and MAO for healthy adult men and women are shown in Table 2. The PAO and MAO are a reflection of the total parietal cell mass and vary with age, sex, body weight, and lean body mass. They are lower in women than in men. Studies have shown that this difference is not only due to the lower parietal cell mass but is also due in part to a decreased sensitivity of the parietal cell mass to gastrin and other stimulants of acid secretion in women. The reason for the latter observation is not known. Maximal

secretory capacity is lower in children than in adults but comparable when expressed as a function of body weight. Both PAO and MAO are reproducible in the same subject day after day and over a long period of time. However, in the elderly there is a decline in gastric acid secretion.

**Continuous *in vivo* intragastric titration** This technique is used to measure the gastric acid secretory response induced by a meal. The gastric pH is raised to 5.5 by the infusion of sodium hydrogencarbonate or hydroxide. A homogenized test meal, also with a pH adjusted to 5.5, is ingested or instilled through a nasogastric tube. For a period of 4 h thereafter, frequent aspirations of 2–3 ml samples of gastric fluid are obtained, the pH is quickly determined and then returned to the stomach. Whenever the pH is observed to drop, sodium hydrogencarbonate or hydroxide is infused into the stomach to maintain the pH at 5.5. The amount of sodium hydrogencarbonate or hydroxide (in mmol h<sup>-1</sup>) required to keep the pH at 5.5 is equal to the rate of postprandial gastric acid secretion. The method is reproducible and is the simplest of the methods used to measure meal-stimulated gastric acid secretion. A major criticism of this method is that the pH is maintained at an unphysiological level which is associated with rising levels of serum gastrin and which could cause alterations in gastric acid secretion.

**Serial dilution indicator technique** This technique, also used to measure meal-stimulated acid output, utilizes a dye dilution and double sampling technique to calculate gastric volume and the rate of gastric emptying. The principle is based on ascertaining the volume of fluid in the stomach by determining the increase in the concentration of a dye (phenol red) produced by the addition of a small concentrated measure of the same dye. By determining the concentration of the solution before ( $c_1$ ) and after ( $c_3$ ) addition of a known concentration ( $c_2$ ) and volume ( $V_2$ ) of the dye, the original gastric volume ( $V_1$ ), can be calculated from the equation

$$V_1 = V_2 \frac{c_2 - c_3}{c_3 - c_1}$$

By measuring the H<sup>+</sup> concentration of the gastric juice and from the gastric volume ( $V_1$ ) obtained, the acid secretory rate can be calculated. The results obtained by this method are similar to those obtained by the continuous *in vivo* intragastric titration method. The method is easy to perform, convenient, does not alter intragastric pH, and the volume calculations are independent of any action of the

dye in the stomach; it also allows multiple measurements of total gastric volume and simultaneous measurement of the rate of gastric emptying during the study. Disadvantages of the method are that it does not consider contributions from swallowed saliva and possible duodenogastric reflux. It is also a cumbersome method and its use has been limited to research investigations.

**Meal-stimulated acid output** The rate of gastric acid secretion following a meal (food is the most important physiological stimulus of gastric acid secretion) is measured by *in vivo* intragastric titration and by the serial indicator dilution techniques. Meal-stimulated gastric acid secretion reaches a peak in about 90 min (**Figure 1**) after the meal. It is not significantly affected by the temperature of the meal or postprandial exercise. In contrast, postprandial intragastric pH increases above 3.0 within 60 min after the meal, an effect attributed to the buffering effect of the proteins in the food. The pH decreases to below basal levels (pH 2.0) in about 2 h after the meal when the acid secretion rate is still relatively high. The latter effect is thought to be the result of complete utilization of the protein food buffers and/or its gastric emptying.

**Measurement of 24-h intragastric pH, acidity, and secretion** Using the techniques of gastric aspiration combined with *in vivo* intragastric titration (only in the postprandial periods), 24-h profiles of the intragastric pH and acidity, and total acid output have been obtained. **Figure 2** shows the results obtained from one such study conducted in healthy adult men and duodenal ulcer patients. Average 24-h acid secretion was 208.30 mmol in the normal subjects and 408.30 mmol in the duodenal ulcer patients. About two-thirds of the acid secreted in the normal subjects was during the day (9 a.m. to 9 p.m.) and about one-third was during the night (9 p.m. to 9 a.m.). Gastric aspiration has been criticized as unphysiological because it may increase acid secretion and stimulate duodenogastric reflux. Also, the repeated hourly aspirations of gastric samples is laborious, confines the subject, and can be uncomfortable especially at night.

Another method of assessing 24-h intragastric acidity but which cannot measure volume and hence acid output, is the continuous monitoring of intragastric pH (pH-metry) with an electrode attached to the tip of the nasogastric tube. The bipolar glass pH electrode is the most widely used type. It is small, 2 to 4 mm in diameter, has a linear pH range (0–12), good response time (<2 s), and an electrode error of less than 0.05 pH. Other electrodes that are in use

**Figure 1** Mean ( $\pm$  SE) acid secretion (top) and intragastric pH (bottom) following an eaten sirloin steak meal. On one day (top), acid secretion was measured by *in vivo* intragastric titration to pH 5.5 in six subjects. On a second day (bottom), intragastric pH was allowed to seek its natural level in ten subjects. The mean ( $\pm$  SE) basal acid secretion rate (top) and basal pH (bottom) prior to the meal are shown at 0 min. Peak acid output (PAO) is also indicated. (Reprinted with permission from Feldman M (1989) Gastric secretion in health and disease. include the monocrystalline antimony electrode (unipolar, hence requires a skin reference electrode), the ion-sensitive field effect transistor electrode (ISFET), and the polymeric membrane electrode. Disadvantages of this pH monitoring technique are: it only reflects the  $H^+$  activity, maintaining stable electrode placement can be difficult and may affect the results, and the equipment may develop technical problems. The advantages are: it is not

**Figure 2** Mean hourly gastric acid secretion during a 24 h period in eight unoperated duodenal ulcer patients and in seven normal men. Breakfast, lunch, and dinner were infused at 9 a.m., 2 p.m., and 7 p.m., respectively. Hourly acid secretion rates are plotted at the end of each hour. (Reprinted with permission from Feldman M and Richardson CT (1986) Total 24-hour gastric acid secretion in patients with duodenal ulcer: comparison with normal subjects and effects of cimetidine and parietal cell vagotomy. *Gastroenterology* 90: 540–544; © W.B. Saunders Company.)

labour-intensive and the study can be conducted with the subjects ambulatory and in their normal daily environment.

**Measurement of other constituents of gastric juice** The methods used to measure the other components of gastric juice, which include hydrogencarbonate, intrinsic factor, pepsin, proteins, other electrolytes ( $\text{Na}^+$ ,  $\text{K}^+$ , and  $\text{Cl}^-$ ), and mucus, are summarized in Table 3. The principles or procedures, disadvantages and, in some cases, the range of normal values are also listed.

## Significance and Interpretation of Results

### Disease-Associated Changes in Gastric Acid Secretion

The disorders associated with abnormal gastric secretion rates and the frequency with which the abnormality occurs are listed in Table 4. In the Zollinger-Ellison syndrome (ZES), basal acid secretion rates are 60% of maximal or greater ( $\text{BAO}/\text{PAO} \geq 0.6$ ). In addition, decreased gastric acid secretion is rarely seen in patients with the somatostatinoma syndrome, a condition associated with an islet cell tumor that secretes excessive amounts of somatostatin, a hormone that inhibits acid secretion. There are recent reports of decreased gastric acid, pepsin and intrinsic factor outputs as part of a gastric

secretory failure in patients with the acquired immunodeficiency syndrome. Disorders in which there is oversecretion of histamine, for example, systemic mastocytosis, foregut carcinoid tumors, and basophilic leukemia are rare causes of acid hypersecretion. Raised intracranial pressure from head injury, although uncommon, is also a cause of acid hypersecretion.

### Testing Completeness of Vagotomy

Absolute values for BAO and PAO that indicate a complete vagotomy and/or antrectomy are not available. Nevertheless, two tests that assess the integrity of the vagal innervation and efferent vagal pathways of the gastric parietal cell and acid secretion have been used in assessing the completeness of vagotomy. These are the insulin hypoglycemia test and the sham feeding test. The use of pepsin secretion in response to sham feeding in testing for the completeness of vagotomy has been recently introduced with good results. However, further clinical evaluation of the test is required to establish its clinical usefulness.

**Insulin-induced hypoglycemia test** The insulin-induced hypoglycemia test (Hollander test) is based on the assumption that hypoglycemia induced by administration of insulin stimulates the vagal centers in the hypothalamus, leading to an increase in gastric acid secretion mediated primarily through the vagal efferent supply of the stomach. Vagotomy will abolish or markedly reduce insulin hypoglycemia-induced gastric acid secretion. Tolbutamide has also been used for performing this test.

The results of this test are difficult to interpret and insulin-induced hypoglycemia stimulates acid secretion through nonvagal mechanisms as well. More importantly, insulin (and tolbutamide) may induce cerebral hypoglycemia, resulting in seizures, coma, and death. Myocardial infarctions, dysrhythmias induced by hypokalemia and release of catecholamines leading to death have also been reported during this test. Because of these problems, the test has been virtually abandoned in most centers around the world. It is being replaced by the sham feeding test.

**Sham feeding test** This is a recently introduced test in which the subject sees, smells, tastes, and actually chews appetizing food but does not swallow it. The accompanying sham feeding-stimulated gastric acid secretion is believed to be mediated through efferent vagal pathways. Studies have shown that sham feeding stimulates as much acid secretion as  $0.1 \text{ U kg}^{-1}$  of intravenous regular insulin and that an adequate

**Table 3** Summary of methods, their principles and/or procedures, and disadvantages for the measurement of other constituents of gastric juice

Constituents	Methods	Principle/procedure	Disadvantages	Normal values
Hydrogencarbonate	Titrateable alkalinity	Back-titration of alkaline gastric juice with HCl to neutrality (pH 7.0)	Requires the absence of acid	$236 \pm 48 \mu\text{mol h}^{-1}$
	pH and $\text{pCO}_2$ method	Measurement of pH and $\text{pCO}_2$ of gastric juice and calculation of hydrogencarbonate concentration from Henderson-Hasselbalch equation	May be affected by loss of $\text{CO}_2$	$366 \pm 23 \mu\text{mol h}^{-1}$
	Two-component method	Assumes fixed ratio of osmolality of plasma to osmolality of nonparietal secretion	Requires the presence of acid	$2600 \pm 600 \mu\text{mol h}^{-1}$
Intrinsic factor (IF)	Coated charcoal method	Charcoal separation of free IF from IF-bound radioactive vitamin $\text{B}_{12}$ ( $^{57}\text{CoB}_{12}$ )	Result affected by temperature, period of incubation, pH, and concentration of reagents	Basal output: $100\text{--}8000 \text{ ng h}^{-1}$  Stimulated output: $1000\text{--}30\,000 \text{ ng h}^{-1}$
Pepsin	Modified Anson and Mirsky method	Protein digestion of substrates and estimation of the soluble or dialyzable digestion products	Result affected by temperature, type of substrate used, pH, and duration of incubation	
Proteins				
Total proteins	Biuret reaction	Precipitation of neutralized gastric juice with tungstic acid and biuret reaction		
Protein components	Biuret reaction and cellulose acetate electrophoresis	Precipitation of neutralized gastric juice with tungstic acid and biuret reaction; separation of protein fractions		Gastric albumin clearance: $14\text{--}39 \text{ ml } 24 \text{ h}^{-1}$
Other electrolytes				
$\text{Na}^+$	<sup>a</sup> AES (Flame) <sup>b</sup> AAS			
$\text{K}^+$	AES (Flame) AAS			
$\text{Cl}^-$	Coulometry Potentiometry with ion-selective electrodes			
Mucus				
Adherent gel layer	<sup>c</sup> Histochemical techniques	Evaluates quantity of acid and neutral mucoproteins in stained tissue sections	Qualitative	
	<sup>c</sup> Incorporation of radiolabeled components of mucoproteins	Evaluates rate of synthesis of the glycoproteins in mucus	Complex; gives no information on protective ability of mucus	
	<sup>c</sup> Gel filtration methods	Analyzes glycoprotein fractions	Complex	
	Estimation of gel layer thickness	Microscopic examination of mounted mucosal sections; slit lamp and pachymeter	Not applicable <i>in vivo</i>	$190\text{--}600 \mu\text{m}$
	<sup>d</sup> Measurement of spinability of mucus (ability to form threads)	Relates spinability to viscoelastic property of the mucus	New technique; requires further evaluation	

Continued

Table 3 Continued

Constituents	Methods	Principle/procedure	Disadvantages	Normal values
Soluble	Measurement of sialic acid in gastric juice	Uses sialic acid as an index of mucus secretion	Insight about mucus viscosity and protective property limited	
	Chromatographic techniques	Analyses of separate mucus fractions	Results difficult to interpret	
	Measurement of single mucus components	Measures the concentrations of the mucus components	Results difficult to interpret; affected by presence of bile	
	Estimation of acid and neutral mucoproteins	Evaluates prevalence of acid and neutral mucoproteins in gastric juice	Results unreliable in the presence of duodenogastric bile reflux	
	Estimation of the mucoprotective index: ratio of neutral to total (acid + neutral) mucoproteins $\times 100$	Assumes that neutral mucoprotein content is an index of the viscosity and protective properties of the mucus	Qualitative character of mucus indirectly related to its protective capacity	$67 \pm 7\%$
	Measurement of mucus viscosity	Relates viscosity to protective capacity	Accuracy of results uncertain

<sup>b</sup> AAS = atomic absorption spectrometry.

<sup>c</sup> Can only be used in resected human gastric specimens.

<sup>d</sup> Can be applied in humans *in vivo*.

vagotomy abolishes sham feeding-stimulated gastric acid secretion.

The appetizing meal consists of sirloin steak, French-fried potatoes and water, but varies between laboratories. Subjects are advised not to swallow the food as it invalidates the test and has to be repeated if it happens. The subject is asked to start chewing the food after 1 h of BAO measurements. During sham feeding (lasts about 30 min) and for 30 min thereafter, serial 15-min samples of gastric contents are aspirated. The sham feeding-stimulated acid output (SAO) is the sum of the four consecutive 15-min period outputs during sham feeding. At the end of the sham feeding hour, a subcutaneous injection of pentagastrin is given to start the third hour of PAO measurement. In patients with vagotomy, it has been determined that  $12 \mu\text{g kg}^{-1}$  of pentagastrin, rather than the normal dose of  $6 \mu\text{g kg}^{-1}$ , is needed to stimulate a maximal acid secretory response. Values for BAO and PAO are obtained as described above.

In nonvagotomized subjects, the SAO/PAO ratio is approximately 0.40 with a lower limit of 0.10 (95% confidence limits). Approximately 70% of vagotomized subjects with no clinical evidence of ulcer recurrence have SAO/PAO ratios of less than 0.10 indicating an adequate vagotomy. Most vagotomized subjects have SAO/PAO ratios of zero. A false increase in SAO can occur from accidentally swallowing food (which may increase acid secretion) during a test and a false decrease in SAO may occur from the

buffering effect (neutralization of acid) of swallowed food. In cases where PAO values are extremely low, close to zero, the results should be interpreted cautiously as the SAO/PAO ratio will be misleadingly higher than 0.10.

### Other Constituents of Gastric Juice

The clinical importance of abnormal gastric  $\text{HCO}_3^-$  secretion is not well understood. More studies are required to define precisely the role of secreted hydrogencarbonate in ulcer disease. Intrinsic factor secretion is increased in duodenal ulcer disease and in other gastric hypersecretory states. Markedly reduced or absent IF secretion occurs in atrophic gastritis with or without pernicious anemia, juvenile pernicious anemia, gastric cancer, large gastric ulcers in the corpus and in partial gastrectomy with complete disappearance of pernicious anemia. In Ménétrier's disease (giant hypertrophic gastropathy), gastric albumin clearance and the protein concentration of gastric juice are markedly increased. Hypertrophic hypersecretory gastropathy is a condition also associated with an increased loss of proteins in the gastric juice but can be differentiated from Ménétrier's disease by a finding of hyperchlorhydria instead of the hypochlorhydria or achlorhydria associated with the latter. Normal ranges of values for the other electrolytes present in gastric juice are not available because of the significant intersubject variations of

**Table 4** Disorders associated with abnormal rates of gastric acid secretion

Disorder	<sup>a</sup> Frequency (%)
<i>With abnormally low acid secretion rates</i>	
Chronic atrophic gastritis	100
Pernicious anemia	100
Vitiligo	20–25
Alopecia areata	6
Rheumatoid arthritis	10–20
Thyrotoxicosis	10
Gastric ulcer	Common <sup>b</sup>
Gastric carcinoma	50
Ménétrier's disease	75
Chronic renal failure	13 <sup>c</sup>
Iatrogenic <sup>d</sup>	
Postvagotomy, postantrectomy	> 90
Medical – e.g. substituted benzimidazoles, potent H <sub>2</sub> -receptor antagonists	> 80
<i>With abnormally high acid secretion rates</i>	
Duodenal ulcer	40–45
Zollinger-Ellison syndrome (ZES)	100
Hyperplasia or hyperfunction of antral gastrin cells	> 90
Hypertrophic hypersecretory gastropathy	100
Massive resection of the small intestine	50 <sup>e</sup>
Systemic mastocytosis	Rare <sup>f</sup>

<sup>a</sup> Some figures shown in this column are extrapolations based on estimates in the literature.

<sup>b</sup> Precise figures are not available; rates of gastric acid secretion tend to be lower than normal, particularly when ulcers are located in the corpus.

<sup>c</sup> Rates of acid secretion are usually normal and can be elevated in some cases.

<sup>d</sup> The purpose of surgical and medical therapy is to lower the rate of acid secretion. Vagotomy is incomplete in ~10% of cases, and the effects of antisecretory medication are dose-dependent.

<sup>e</sup> Hypersecretion of gastric acid is generally transient, and rates return to normal within weeks of the operation.

<sup>f</sup> Hyperchlorhydria is rarely observed, and most often acid secretion is normal or even decreased.

the values obtained in reported studies. Furthermore, since the clinical significance of the Na<sup>+</sup>, Cl<sup>–</sup>, and K<sup>+</sup> content of gastric juice are not known, their measurement has been limited to specific research investigations. Despite the numerous techniques listed for the measurement of mucus in gastric juice, their complexity, uncertain value, and technical problems still hinder successful application in man. Hence, there remains the need to develop a method that is accurate, reliable, easy to use, and that directly assesses the quantity and protective role of gastric mucus.

## Specific Problems

### Contamination and Neutralization

Contamination of gastric juice and loss of H<sup>+</sup> can result from dilution and neutralization by alkaline gastric secretion, hydrogencarbonate-containing saliva, esophageal secretion, and duodenal and pancreatic secretions through duodenogastric reflux. Hydrogen ions can also back-diffuse and be lost into the gastric mucosa. These losses of H<sup>+</sup>, although leading to an underestimation of the rate of gastric acid secretion, are believed to be small relative to the rate of acid secretion. The losses are generally ignored in routine clinical tests of gastric acid secretion.

**Saliva** Contamination of gastric juice by saliva can be prevented by continuous suction using a dental suction set during gastric secretory tests. Inserting dental cotton wool packs between the gums and cheek to absorb any secreted saliva, and instructing study subjects to spit out and avoid swallowing saliva are other methods that have also been used to prevent salivary contamination of gastric juice.

**Esophageal secretions** Contamination of gastric juice samples by esophageal secretions has not been investigated. However, recent studies show that the esophagus secretes basal hydrogencarbonate.

**Duodenogastric reflux** Visible bile staining of gastric juice signifies duodenogastric reflux with the possibility of contamination with pancreatic and duodenal secretions. Such samples should be discarded.

### Isolation and Stability of Gastric Juice

Gastric juice collected for analyses should be stored on ice until the analyses can be performed. If analysis is delayed for more than 4 h, the samples should be stored in a refrigerator. Samples collected for IF and protein determination should be stored on ice until they can be depepsinized and the assay performed or stored in a refrigerator. The samples can be stored for 5 days with only 7% loss of IF activity. Samples for the estimation of pepsin should be stored in a refrigerator for not more than 1 week to ensure retention of significant peptic activity. For periods greater than 1 week, gastric juice mixed with glycerol can be stored at –20°C for many months without loss of peptic activity.

## Acid Secretory Tests

Over the past four decades, measurement of gastric acid secretion has been markedly improved by

advances in electrochemistry and technology, particularly the development of precision pH and titration equipment, and computer hardware and software. Despite these improvements, there has been a decline in the requests for tests of gastric acid secretion by physicians. The reason for the decline in the use of acid secretion tests is mostly due to the availability of more accurate and easier diagnostic tests. These include serum measurements, e.g. of gastrin and vitamin B<sub>12</sub> in ZES and pernicious anemia respectively, radiology and particularly endoscopy and biopsy. It is also due in part to the observed decline in the incidence of peptic ulcer disease and perhaps to the inconvenience and cost of acid secretion tests. Nevertheless, acid secretory tests may still be used as important adjuncts to the more specific tests in the following situations:

(1) In patients with peptic ulcer disease (duodenal ulcers) on medical treatment whose ulcer fails to heal after 12 weeks of treatment. The tests may establish the reason for the failure, e.g. a missed gastrinoma, reveal the need for a higher therapeutic drug dosage, or even establish the need for a switch to a more potent antisecretory drug.

(2) In routine pre- and postoperative assessment of patients undergoing surgery for peptic ulcer and in the assessment of recurrent ulcers in postgastrectomy and postvagotomy patients. In this case, the sham feeding test is a most valuable tool for evaluating the surgical procedure used and the skills of the operating surgeon.

Acid secretory tests remain the best research tools for investigating normal and abnormal gastric function and the best tests for evaluating the effective suppression of meal-stimulated gastric acid secretion, a mandatory test of the therapeutic effectiveness of antisecretory drugs. Measurement of 24-h intragastric pH, a new trend, has become increasingly easier

to perform, and is more convenient than gastric aspiration. However, for clinical usefulness, further improvement in the analysis of the results is needed.

## Introduction

Geochemistry is the study of the chemistry of natural earth materials and the chemical processes operating within and upon the Earth, both now and in the past. Geochemical analyses are carried out on any natural sample such as air, volcanic gas, water, dust, soil, rock or biological hard tissues (especially ancient biological tissues) and also on anthropogenic materials such as industrial effluent and sewage sludge. Geochemical analyses therefore involve a wide range of materials and analytes of interest and may be performed for industrial, environmental, or academic reasons. All of the naturally occurring elements in the periodic table are important for one geochemical investigation or another. Element concentrations may range from major or minor constituents ( $>0.1\%$ ) in one material to trace levels (usually expressed in  $\mu\text{g g}^{-1}$  (parts per million) or  $\mu\text{g kg}^{-1}$  (parts per billion)) in another. Geochemical tracers are commonly employed to investigate geological processes that are necessarily inaccessible to direct observation. Such tracers frequently demand high precision analysis of trace element abundance or isotopic ratio, and the demands of inorganic geochemists have played a significant role in the development of high precision multielement analytical techniques. Geological materials are commonly refractory substances and may require aggressive chemical preparation prior to analyses. Several articles in this volume deal specifically with the chemical analysis of soils, waters, and biological tissues, and organic geochemistry is also covered separately. This article concentrates on analysis of the inorganic constituents of the materials most closely associated with geology – rocks.

## The Nature of Geological Materials

Rocks of the upper portion of the Earth's crust are divided into three main types: igneous, sedimentary, and metamorphic rocks. Igneous rocks such as basalt, granite, gabbro, and rhyolite form from crystallization of mainly silicate liquids and are therefore primary rocks. Igneous rocks make up around 95% of the crustal volume, but only around 25% of the crustal area. Metamorphic rocks such as gneiss, schist, and slate are formed when existing rocks are subjected to high temperatures and/or pressures, and are commonly exposed in ancient cratonic regions of the continents. Sedimentary rocks such as sandstone and limestone are formed from the consolidation of weathered and eroded components of other rocks, or from chemical or biological precipitation of minerals from solution at the Earth's surface. Sedimentary rocks account for only 5% of the crustal volume, but around 70% of its area.

Rocks are composed of grains or crystals of one or more minerals. Although there are many thousands of naturally occurring minerals, most rocks are composed from a restricted suite, collectively known as the rock forming minerals. The composition of 29 of the most common rock forming minerals is shown in **Table 1**. The Earth is chemically differentiated, with dense ferromagnesian elements concentrated in the core and mantle, lighter rock forming elements such as Al and Si concentrated in the crust, and the lightest elements forming the atmosphere. The bulk composition of the different layers of the Earth are shown in **Table 2** and the average composition of the main rock types within the crust are shown in **Table 3**. The most abundant elements in the crust are Si, Al, and O, which together comprise around 73% of the crust. Most minerals are therefore silicates, and chemical analysis of rocks is focused on determination of elements in a silicate matrix.

## Applications of Geochemical Analyses

Given the broad definition of geochemical analyses it is unsurprising that the applications to which

**Table 1** Composition and classification of major rock forming minerals

<i>Classification</i>	<i>Group</i>	<i>Mineral</i>	<i>Composition</i>
Native elements	Metals	Gold	Au

geochemical analyses are put are equally wide. Some examples are shown below:

- ‘Identifying unknown natural materials’. Mineral identification (petrology) may be performed by a combination of microscopy, X-ray diffraction and chemical analyses. Electron-probe microanalysis (EPMA) is particularly valuable in mineral identification as the technique combines spatially resolved quantitative determination of major elements with the imaging capabilities of the scanning electron microscope.
- ‘Assessing the quality of a product’. Geochemical analyses are a vital tool in the metal extraction industry where a few micrograms per gram may represent an ore for some elements. Ores may also contain significant concentrations of toxic or polluting trace elements. Phosphate ore, for instance, may

contain 50 mg kg<sup>-1</sup> Cd, which will be concentrated and potentially released during processing of the ore.

- ‘Reconstructing the history of a rock’. Many important geological processes are either extremely slow and/or occur at great depths within the crust where they cannot be observed directly. Rocks and the minerals from which they are composed form under specific temperature and pressure conditions, in contact with fluids of particular composition. The trace element and stable isotopic composition of the mineral components in a rock provide a record of these conditions and can be used to reconstruct fundamental geological processes occurring within the Earth. Rocks and minerals (especially biominerals) that form at the Earth’s surface provide a geochemical record of conditions at the Earth’s surface through time.

**Table 2** Bulk composition of the whole Earth, and major geological divisions of the Earth

- ‘Dating rocks’. The absolute age of rocks may be established through radiometric dating. The ratio of radiogenic and stable isotopes of a single element in a mineral is related to the original concentration of the radiogenic isotope at the point when the mineral formed, and the time elapsed since formation. Several geochronometers are currently used, including those based on Rb–Sr, Nd–Sm, Lu–Hf, K–Ar, Ar–Ar, and the U–Pb decay series. Reliable dating requires accurate and precise measurements of isotopic ratios (for instance the  $^{87}\text{Sr}/^{86}\text{Sr}$  ratio of a clay mineral with an initial  $^{87}\text{Rb}/^{86}\text{Sr}$  ratio of 5 will increase by only  $\sim 0.00007$  in a million years). Clearly, accurate dating requires extremely accurate determination of isotope ratios.

- ‘Temporal variation in concentrations of elements and isotopic ratios’. Geological materials often form over long timescales and therefore provide time-resolved measurements of the natural (or anthropogenic) distribution of elements. Much attention has recently focused on assessing geochemical variation in materials that grow more or less constantly – so that spatial variation in analytes across the sample corresponds to temporal variation in the distribution of those elements or isotopes over time. This application has been used widely to determine paleoclimate fluctuations from ice cores, speleothems (e.g., stalactites and stalagmites), corals, and other incrementally grown records.

- ‘Spatial distribution of elements’. Mapping the spatial distribution of elements across land surfaces provides important information on soil chemistry, pollution and transport of nutrient and toxic elements through the soil. In this instance large numbers of analyses are frequently required so analytical techniques must be rapid and protocols standardized to cope with a wide range of sample matrices.

- ‘Determining source or provenance of natural materials’. The trace element and isotopic composition of minerals is controlled by the environment of formation and can therefore be used to discriminate

**Table 3** Working values for elemental composition in commonly used reference materials. Note that minor and trace element composition may vary greatly within major rock types

between rocks or minerals formed in different places. Geochemical provenance analysis has many applications including establishing prehistoric trade routes for obsidian artifacts, identifying products of large historical volcanic eruptions, and tracking the illegal trade in fossil bones.

## Analytes of Geological Importance

As mentioned above, virtually the entire periodic table is used in some geological applications. The growth of multielement techniques such as XRF and latterly inductively coupled plasma-atomic emission spectrometry (ICP-AES) and inductively coupled plasma-mass spectrometry (ICP-MS) has led to an increasingly wide suite of elements being determined routinely in geochemical analyses. Certain groups of elements are particularly important analytes in geochemical analyses.

### Group 2 Elements

The group 2 elements are major constituents in many rock forming minerals, particularly in low temperature

carbonate systems. Substitutions of group 2 elements for calcium are at least partially temperature dependant, and as biomineralized tissues such as shells and coral form in equilibrium with seawater, Ba/Ca, Sr/Ca, and Mg/Ca ratios in historic and ancient biominerals are frequently employed as paleotemperature proxies and as records of ocean chemistry.

### Transition Elements

The transition elements are useful tracers in many geological systems. They are industrially important and form economic ores, especially in hydrothermal systems where they are often present as sulfide minerals. Cd, Hg, Zn, and Pb are persistent industrial pollutants and determination of low levels of these elements in ores and fossil fuels is critical as processing of ores or burning of fuels may concentrate and release toxic elements. The concentration of such toxic trace elements may affect the economic value of an ore or fossil fuel deposit significantly.

### C, N, O, S, H

The isotopic composition of light elements in geological materials provides abundant evidence of formation processes in rocks, including temperature of crystallization, salinity, redox conditions, evidence of bacteriological processes, and dietary composition.

### Halogens

Halogens are relatively infrequently determined in geological materials, but may be important constituents of some rock forming minerals (e.g., apatite Table 1). Increasingly, the connection between the geological distribution of elements and endemic nutrient deficiency is being recognized. For instance, goiter is the expression of I deficiency in humans, and is endemic in areas where bedrock is deficient in I. Regional geochemical mapping may help to identify areas where dietary mineral supplements could alleviate endemic mineral deficiencies.

### Rare Earth Elements (REE)

The lanthanides or rare earth elements are particularly useful in geological analyses, as their similar chemical properties but smoothly decreasing ion radius make them ideal tracers for many geological and environmental processes. The REE have been used as tracers of magma mixing, to establish provenance of archaeologically traded artifacts, to examine hydrological mixing processes and to reconstruct redox conditions in ancient oceans. The isotopic composition of Nd provides a valuable tracer for past and present oceanic mixing – a key to understanding

global climate dynamics. The REE also form natural analogues for radioactive products of the nuclear industry, and provide two radiogenic dating schemes (Lu/Hf and Sm/Nd). Separation and analysis of the REE is difficult due to their similar chemistry and relatively low abundances in many natural materials. Analysis of the REE in geological materials was instrumental in development of ICP-MS technology.

### Platinum Group Elements (PGE)

The platinum group elements are among the most valuable naturally occurring elements largely due to their scarcity. In addition to their economic importance, the PGE provide useful tracers of certain geological processes. The presence of high levels of iridium in globally distributed sediment layers, for instance, has been taken as evidence of meteoric impact or global volcanism. The PGE are relatively difficult to analyze due to their extreme low abundance, and the resistance of PGE-bearing minerals to acid digestion.

### Sampling

The goal of all sampling is to produce a subpopulation of samples drawn from a natural population that accurately represents the true abundance, distribution, and variation of the analyte(s) in question within the accepted limits of accuracy of the study. Clearly, sample design requires prior knowledge or informed assumptions regarding the distribution of the analyte in question. When analyzing geological materials, sample strategy and design is frequently compromised by the complexity and inaccessibility of suitable geological materials. In addition to general sampling guidelines, specific points should be borne in mind when sampling geological materials:

1. 'Variability of sample type'. Many different types of rock or sediment may be encountered within a single geological survey. These materials may present contrasting challenges for preparation and analysis. Comparisons of analyte concentration in different matrices have lower confidence than analyses of analyte concentrations in similar matrices.
2. 'Spatial variability'. Spatial variation or heterogeneity in analyte concentration is found at all spatial scales. Most rocks are composed of different minerals, and elemental concentration will therefore vary widely within each rock. Further spatial variations occur at outcrop and regional scales. Homogenization of the sample may be required to limit errors associated with variation in single samples, and repeated analyses across an outcrop or across a geographic region may be necessary to

control for variation on larger spatial scales. In rocks, the larger the grain size, the more material must be homogenized to ensure a valid bulk analysis. The investigator must choose between the merits of a bulk analysis and an analysis targeted on a specific mineral where background variation will be less affected by mineralogical and therefore crystal chemical factors.

3. 'Temporal variability'. Geological materials take time to form and thus each sample represents a discrete period of time. As geological processes occur over an almost infinite range of timescales, the amount of time represented by a sample also varies. If time is an important consideration of a study, one must factor in some assessment of time resolution into the sample design. It is impossible, for instance, to use ablation-based analytical techniques with a laser spot size of  $10\mu\text{m}$ , to determine the effect of annual fluctuations in climate or rainfall in a speleothem that grows by less than  $10\mu\text{m year}^{-1}$ . Furthermore, rates of geological processes are generally calculated by simply dividing change in mass/length by time. This implies constant growth rates whereas most geological processes (including mineral growth) occur stochastically.

### **Sample Collection**

Collection of samples in the field may involve simple grab samples of unconsolidated sediments, removal of chips of rock by hammering or mechanical coring or mechanical concentration of samples by panning. If sampling unconsolidated sediment, a simple polythene scoop is sufficient. Depth of sampling will be to some extent determined by the requirements of the study as many elements are actively cycled within sediments particularly at redox boundaries. Choice of sample location may be truly random, or may be manipulated to avoid or seek anthropogenic disturbance.

Collection of rock samples is most easily achieved by removing a chip from the rock surface with a hammer. Representative sampling is difficult to achieve in this manner as accessible surfaces are by definition surfaces that are exposed to weathering. Weathering may significantly alter the elemental composition of a rock, as mobile elements or elements contained in unstable minerals are lost to soil and pore waters, thereby concentrating immobile elements or elements contained in relatively stable minerals. The depth to which an exposed rock is affected by weathering varies with length of exposure, climate, vegetation, mineralogy and porosity of the rock. Sampling at depth within the body of the rock with mechanical rock-coring devices may alleviate

some of these problems, particularly if recovered cores are split and central portions removed for analysis, thus limiting contamination from the metal-coring device.

Storage of rock or rock powder samples presents few problems. However, care should be taken to ensure samples remain dry. Rocks containing minerals that formed under reducing conditions may be susceptible to oxidative decomposition. Many sulfide minerals in particular break down readily if left exposed to moist air.

### **Sample Preparation**

A wide range of analytical techniques are routinely employed in the geochemistry laboratory, and the sample preparation techniques required vary depending on the nature of the material, the type of analysis to be performed and the purpose of the study. In most cases some form of mechanical processing is required. A typical process for preparing solid rock samples for analysis is given below:

- Removal of weathered or contaminated surfaces using a hammer or hydraulic rock breaker.
- Crushing of the sample to gravel or small chips in a reciprocating steel crusher.
- Grinding of the chips to a coarse or fine powder according to the application. A coarse powder, usually sieved to a specific particle size range, is generally required for mineral separation. For bulk analyses, the sample is generally crushed to a fine powder either in a ball mill, or for small sample concentrations, hand ground in a ceramic, agate or corundum mortar.
- Splitting of powder into subsamples for replicate analyses or storage.

### **Bulk Rock or Targeted Analyses?**

Most rocks are aggregates of different minerals. The separate minerals within a rock each have differing major and trace element compositions, providing a complex, heterogeneous sample. Bulk rock analyses provide a picture of the rock as a whole, and are suitable for comparing different examples of particular rock types – for instance contrasting basalts formed at midocean ridges with those formed in island arcs. Whole rock analyses are also used to compare fine-grained sedimentary rocks, as the bulk rock composition reflects an integrated record of all sediment sources contributing to deposition of the final rock.

In many cases, bulk rock analyses are inappropriate and analyses must be targeted. Zircon, for example, is an extremely resistant mineral that can

survive multiple cycles of weathering and transport. Zircon crystals present in sedimentary rocks may have formed in granitic melts billions of years before deposition of the sandstone. Clearly analysis of the chemical composition of zircon crystals within a sandstone will say nothing about the depositional environment of the sand, but may be extremely informative as to the land surfaces eroding to produce that sand. The oldest land surfaces on Earth have been identified and studied through targeted analyses of such refractory minerals redeposited in younger sedimentary rocks.

Elemental partitioning from melt or solution into a crystal is specific to the particular mineral lattice, and monomineralic samples are required for most trace element analyses. Monomineralic analyses may be performed by mechanical separation of mineral grains, or by targeted *in situ* analyses. *In situ* analyses are clearly preferable as sample preparation is much simpler, however, the analytical accuracy and precision currently available via *in situ* analysis methods is not sufficient for all applications, particularly dating of mineral grains. In such cases physical separation of mineral grains is necessary. Mineral separation may be performed by hand picking, especially for isotopic work where relatively small sample sizes are adequate. Coarse crushed and sieved powder is spread in a glass dish or on a clean paper sheet and the required minerals are identified under a binocular microscope and removed with fine tweezers.

### Density Separation

Minerals are frequently separated according to their specific gravity (SG). Minerals with a density greater

than 2.87 are referred to as heavy minerals and can be separated from commoner minerals such as quartz, feldspar, and calcite using a 'heavy liquid' separation. A liquid with a SG of 2.87 or above is placed in a separating funnel, and the sample introduced. Dense minerals settle out where they can be retrieved, lighter minerals can be filtered from the heavy liquid. Bromoform (SG = 2.87) was commonly employed as the heavy liquid, but as this liquid is carcinogenic, most laboratories now employ aqueous sodium polytungstate solution (SG = 2.96–3.06 at 20°C).

These physical sample preparation steps may be followed by one or more stages of chemical preparation. Table 4 outlines some analytical techniques commonly employed by geochemists and the sample preparation techniques required. More details are given in technique-specific articles. While some techniques such as EPMA, X-ray fluorescence (XRF), ion microprobe and laser ablation mass spectrometry require little preparation other than presentation of a clean, relatively flat surface, most techniques require either complete or partial digestion.

### Sample Decomposition

All geological materials can be dissolved quantitatively, and there is an extensive literature on the various processes available. The choice of dissolution procedure will vary according to the nature of the sample, the number and size of the samples, the requirements of the analytical technique in terms of analyte concentration and total dissolved solid concentration, volatility of the analytes of interest, precision and accuracy required, contamination from

**Table 4** Summary of analytical techniques commonly employed for specific analytical tasks within geoscience, and preparation that may be required

Analysis	Analytical techniques available	Preparation required
Major-minor elements	EPMA ICP-OES, Flame AA	Polished solid sample Solution
Minor-trace elements	XRF ICP-MS, ICP-OES, Flame, GF AA	Clean surface, pressed powder pellet Solution
Trace elements	XRF ICP-MS INAA	Clean surface, pressed powder pellet Solution

Isotope analysis	MC-ICP-MS SIMS, PIMS SHRIMP IRMS	Solution (may be coupled with laser ablation) Solution, elemental separation (preconcentration) Varied Chemical gas evolution, laser fluorination, thermal combustion

Note that this is a summary of some of the more commonly applied techniques, and does not reflect the total range of techniques employed, or the full range of applications for a particular analytical instrument.

introduced chemicals, the cost and time associated with the procedure and safety concerns. Choice of an appropriate decomposition method is critical for a reliable, accurate and precise method. All dissolution methods must be evaluated through digestion and analysis of certified standard reference materials that as far as possible match the composition of the sample and reagent blanks should always be prepared along with samples. The dissolution method employed must be clearly and entirely described when reporting the results of geochemical analyses as there are few standardized dissolution protocols and the analyses obtained can only be as reliable as the dissolution method employed. Following decomposition, the sample is generally brought up to volume in a suitable matrix (usually dilute nitric acid ( $\text{HNO}_3$ )). The volumes of sample and reagent used and the final dilution will be determined by the concentration of the analytes of interest in the sample and the requirements of the analytical technique. Sample dilution is often a compromise between maximizing the signal for low-level analytes and reducing the total dissolved solid burden.

### **Acid Decomposition**

**Carbonates** Carbonate minerals such as calcite and aragonite, the principle components of limestone and most phosphate and sulfate minerals will dissolve readily in 1 N HCl at room temperature. Chloride ions may be avoided by digestion in  $\text{HNO}_3$ , however, heating may be necessary for some phosphate minerals. Many carbonate and phosphate samples are not pure, and also containing clay minerals which will not be decomposed by HCl or  $\text{HNO}_3$ . Partial digestion is therefore a chemical purification of the target carbonate or phosphate mineral. Trace elements adsorbed onto clay mineral surfaces may, however, be released during HCl/ $\text{HNO}_3$  decomposition of carbonates and phosphates. Reference materials should be subjected to the same partial extraction techniques.

**Sulfides** Sulfides and salts of the hydride-forming elements (Se, As, Te, Sb) are decomposed by  $\text{HNO}_3$ .

**Silicates** Most geological materials are silicates and as these are chemically resistant materials, powerful reagents are required to produce complete digestions. Typically silicate minerals and resistant oxides are decomposed by heating with hydrofluoric acid (HF) and another strong mineral acid with a higher boiling point, usually  $\text{HNO}_3$  or perchloric acid ( $\text{HClO}_4$ ). HF digestion is performed on a hotplate, the solution evaporated to dryness, and the resultant cake

redissolved in a weaker acid (generally 1–2%  $\text{HNO}_3$ ). HF attacks the silicate matrix and silicon is quantitatively removed as volatile  $\text{SiF}_4$ . The presence of the second acid with a higher boiling point than HF ensures that sparingly soluble metal fluorides are converted to more soluble salts on completion of the evaporation.  $\text{HClO}_4$  is preferable to  $\text{HNO}_3$  as it has a higher boiling point and is more effective at dissociating fluorides.  $\text{HClO}_4$  is, however, especially hazardous if samples contain organic materials, is more expensive than  $\text{HNO}_3$  and introduces chloride ions which may cause interferences for mass spectrometric analysis.

Open vessel HF digestion is the most commonly employed decomposition technique for silicate materials but it is not without disadvantages. Some refractory minerals fail to dissolve fully in HF– $\text{HClO}_4$ / $\text{HNO}_3$  including zircon, rutile, cassiterite, chromite and tourmaline. In addition to Si, other volatile metals such as Se, Hg, As, S, Sb and possibly Pb and Cd will be lost during the evaporation stage. Open vessel digestions are also susceptible to airborne contamination. Closed vessel digestions or microwave digestions provide an alternative to open vessel digestions; however, while these techniques may limit loss of volatiles and airborne contamination and may provide a safer working environment, there is no real improvement in dissolution efficiency unless reaction temperatures exceed 200°C. This cannot be achieved with conventional microwave digestions.

### **Partial Digestions (Acid Leaching)**

Complete digestions of rock samples may not be necessary or desirable in some situations. Environmental analyses are typically concerned with bioavailable metals and nutrients. Bioavailable metals are defined by their ease of acid extraction, and are leached from a sample using strong mineral acids such as aqua regia (3:1 mixture of HCl and  $\text{HNO}_3$ ). Consequently there is no advantage to performing a complete digestion. Acid leaching has several advantages over complete mineral digestions. Loss of volatile elements is reduced as no evaporation stage is required, and the total dissolved solid concentration is reduced. This is important in determination of low-level analytes by ICP-MS where a high dissolved solid burden may require further dilution of the sample.

HCl should be avoided if the final analysis is to be performed by conventional ICP-MS or AA, particularly if the analytes of interest are transition elements, as the presence of the chloride ion in the analyte solution produces several persistent analytical interferences. Use of  $\text{HNO}_3$  alone in acid

leaching, however, results in low recovery of available elements. These problems may be circumvented by using cell technology ICP-MS systems where interference problems caused by chloride ions are dramatically reduced.

All partial digestions suffer from a lack of standardized methods and recognized reference materials that can be used to validate decomposition and analytical protocols. Where standards are available, care must be taken to follow the precise leach protocol described in the reference certificate.

### Fusion Techniques

Fusion decomposition provides an alternative digestion method. This is a high-temperature technique where powdered samples are heated with a suitable flux to produce a residue that may be readily dissolved. Fusion decompositions are the most rigorous digestions available and all silicate materials can be brought into a complete solution when fused with an appropriate flux. The principal disadvantage of the fusion technique is the introduction of extra salts into the final solution from the flux (thereby increasing total dissolved solids). Fusion decomposition remains the preferred technique for quantitative analysis of silicon, and may be the only practical method for complete decomposition of refractory minerals such as zircon, rutile, and cassiterite. Many fluxes have been used, but perhaps the most commonly used is lithium metaborate ( $\text{LiBO}_3$ ). This flux introduces only Li and B into the final solution, and is used at a relatively low flux:sample ratio of 3:1.

### Spatially Resolved Analyses

There is currently an explosion in the use of *in situ* analysis techniques, particularly techniques that decompose a small portion of sample by firing a pulse of laser light at the sample surface and transporting ablated particles directly into the analytical machinery (laser ablation). Such *in situ* techniques have the considerable advantage that there is no sample preparation required other than cutting, grinding and polishing the sample, and analyses can be targeted accurately at particular mineral grains or regions of a sample. The sensitivity available using laser ablation techniques is, however, considerably lower than that obtained using the equivalent analytical equipment with solution-based sample introduction. A second problem arises from the difficulty of standardizing the analyses. The amount of material ablated by the laser is a function of its power, the duration of the laser pulse, and the interaction of the laser with the sample surface. As most samples are heterogeneous, the quantity of sample introduced into the analytical

device may vary throughout an analysis. Some of these problems may be minimized through the choice of a suitable laser system. Lasers operating at wavelengths  $<200\text{ nm}$  induce ablation by breaking chemical bonds rather than heating, and this 'cold' ablation results in a reduction of interelement fractionation. The recovered signal is also relatively insensitive to differences in sample matrix allowing more reliable cross-calibration between sample types. Nonetheless, natural materials are generally heterogeneous over distances of a few micrometers, and the amount of sample delivered to the analytical device will vary in an unpredictable way. Effects of uneven ablation may be minimized by standardizing counts for the analyte of interest against those of an element with known and constant concentration throughout the sample. For instance, analyses of trace metal concentrations in ancient shells are often normalized to Ca concentrations within the shell calcite or aragonite. Variation in Ca concentration within the samples may be independently assessed through electron microprobe analysis. Clearly this is only possible in monomineralic samples. It is also difficult to achieve representative calibrations in LA work as calibrations should ideally be performed against matrix matched calibration standards. Few spatially homogeneous calibration standards exist, so calibration is often performed against synthetic glasses or pressed or fused powders, whose composition and ablation characteristics may be very different from the sample. Finally for the same reasons of sample heterogeneity, few standard reference materials are available to assess accuracy of laser ablation analyses. Despite these difficulties, the advantages offered by *in situ* analyses of trace level analytes in geological materials are numerous and LA-ICP-MS is rapidly becoming a mainstream technique in geochemical analysis.

### Analytical Techniques

A huge range of analytical techniques are used by geochemists and applied to geological problems. Some questions may be addressed using more than one piece of analytical equipment, whereas other applications demand specific machine capabilities. A list of the most commonly used analytical techniques is provided in Table 4.

#### Mass Spectrometric Techniques

Inductively coupled plasma mass spectrometry ICP-MS is arguably the work-horse in the modern geochemist's stable, and geological applications have driven many developments in ICP-MS

technology. ICP-MS has largely taken over from atomic absorption and atomic emission spectrometric techniques. Modern ICP-MS systems are capable of analyzing most elements in the periodic table simultaneously at levels of  $10 \text{ pg ml}^{-1}$  with a mass resolution of  $<1 \text{ amu}$ . The major disadvantage of ICP-MS is the formation of polyatomic interferences through interactions of the carrier gas, atmospheric gases and matrix ions. Polyatomic interferences are most problematic over the mass range 31–80, and because of this the main use of ICP-MS in geochemistry has been determination of low-level, high mass ( $>70$ ) elements. Recent development of collision and reaction cell technologies where matrix interferences are reduced or removed prior to detection, and high-resolution ICP-MS capable of resolving mass differences  $\ll 1 \text{ amu}$  have vastly increased the potential for ICP-MS in analysis of lighter, particularly transition, elements and their isotopes in complex geological and environmental matrices.

ICP-MS is easily coupled with laser ablation sample introduction systems giving spatially resolved analyses (smallest spot sizes around  $10 \mu\text{m}$ ) with working detection limits of  $\sim 1\text{--}10 \text{ mg kg}^{-1}$ . High-resolution ICP-MS may be coupled with LA introduction systems to provide high spectral resolution with rapid scanning across the entire mass range. This is particularly important when analyzing small sample volumes such as fluid inclusions, where the entire sample is rapidly consumed.

**Thermal ionization mass spectrometry (TIMS) and multicollector ICP-MS** The dating of geological materials requires highly accurate determination of isotopic abundances. This is generally achieved using a magnetic sector mass analyzer and faraday cup detection system. TIMS is commonly used to for radiometric dating and for investigations of mixing of water masses using (for instance) Sr, Nd, and U-series isotope systems.

Recently magnetic sector, multicollector ICP-MS has been used to determine isotope ratios with similar precision to TIMS. As production of the ion beam in ICP-MS is not dependent on ionization efficiency, a wider range of isotope systems may be analyzed. The development of multicollector ICP-MS has demonstrated the existence of significant isotopic variations among a wide range of materials, and many potential new geochemical and biogeochemical isotopic tracers are under investigation. The isotopic composition of Fe, Cu, Zn, and Ca in particular offer great potential as geochemical and biogeochemical tracers. Despite the problems associated with *in situ* analyses, multicollector ICP-MS may be coupled to a laser ablation system, as instabilities in analyte

supply caused by uneven ablation are offset by the rapid simultaneous detection in multiple faraday cups. Unlike high-resolution quadrupole ICP-MS, however, MC-ICP-MS systems are inherently incapable of rapidly scanning over a wide mass range. The application of MC-ICP-MS to the analysis of geological materials is in its infancy, and the field is expanding rapidly.

### X-Ray Fluorescence

XRF provides high precision analyses of major and minor elements in a wide variety of samples including rocks. XRF analyses are usually performed on pressed powder pellets of the ground sample, mixed with an organic binder. One distinct advantage of XRF analysis, therefore, is that samples do not need to be decomposed prior to analysis. This may compensate for the relatively high limits of detection of XRF ( $>1 \text{ mg kg}^{-1}$ ) for many elements, as samples need not be diluted. Quantitative determination of trace elements in rock samples by XRF requires calibration against matrix-matched geological reference materials. Fortunately a great variety of geological reference materials have been developed and a suitable reference material may be obtained for most rock types.

Synchrotron radiation also has many applications in geological sciences, particularly for determination of the local environment, geometry, and coordination of a specific element. Synchrotron sources can be used in XRF analysis, providing high-resolution elemental maps. Synchrotron-based X-ray investigations are frequently used to investigate the sorption of elements onto mineral or particle surfaces.

### Electron Probe Microanalysis

EPMA combines the imaging capability of a focused electron beam with the analytical potential afforded by induced X-rays to produce spatially resolved analyses of a wide range of elements with a limit of detection of  $\sim 100 \text{ mg kg}^{-1}$ . EPMA has many uses in geological science, particularly in mapping the spatial distribution of major and minor elements within solid samples. Samples are prepared by embedding in a resin or polymer matrix and polishing to yield a flat surface. Calibration is performed against mineral standards. The development of alternative spatially resolved analytical techniques with lower limits of detection has to some extent superseded the use of EPMA in geochemical analyses, but the combination of elemental mapping with high-resolution imaging within an electron microscope remains useful.

## Miscellaneous Techniques

Mineral identification may be performed using polarized light microscopy, but where possible single-crystal or powder X-ray diffraction is the technique of choice for determining mineral structure. Fourier transform infrared spectrometry (FTIR) is also commonly used to identify mineral structure and determine crystal perfection in geological materials.

## Standards and Standardization in Geochemical Analysis

The performance of any analytical procedure must be assessed through analysis of certified reference materials. As geological materials are varied, often with complex heterogeneous matrices, artificially produced standards are seldom sufficient. Homogenized, certified standard reference materials are available for a wide range of rock, soil, mineral, and biomaterial types and must be used to validate analytical protocols. Interlaboratory comparisons of measurements of the elemental and isotopic composition of reference materials are frequently published in dedicated journals such as the *Geostandards Newsletter*.

## Introduction

This article covers general methods applicable to the physical and chemical analysis of sediments from lakes, rivers, estuaries, and coastal seas. The material fluxes from the land to the sea are dominated by the sediment loads delivered by the global rivers. Although the river sediment flux cannot be predicted accurately, it is thought to be in a range from 10 to 20 Gt a<sup>-1</sup>. Contributions by individual rivers are conditional upon the geology, topography, and climate of their drainage areas. Much of the sediment transported by rivers is temporarily stored

in the lower part of the river basin and often only reaches the ocean by slow migration through its estuary. Although there are compositional differences between sediments from these environments they generally comprise highly variable and complex mixtures of aluminosilicate particles, quartz grains, terrestrial organic detritus, planktonic material, and ferromanganese oxides. The surfaces of mineral phases, such as clays, are modified by coatings of organic matter and iron and manganese oxides. The various particle types in a sedimentary assemblage have unique surface properties that influence their chemical reactivity with dissolved constituents. Thus, particle–water interactions, which are accentuated in estuaries because of the sudden change in reaction conditions across the freshwater–seawater interface, give rise to complex array of adsorbed and absorbed species of inorganic and organic

constituents. Depending on their grain size, carbon content, and the length of time deposited at the site, consolidation of sediments may occur and anaerobic conditions may also develop in the sediment column, as a consequence of the bacterially moderated decomposition of particulate organic matter. Consequently, the focus of analytical methods for metals, radioisotopes (including metals, nonmetals, and metalloids) and persistent organic pollutants have become highly oriented to preserving, detecting, and quantifying the concentrations of particulate species in sediments and to establishing their relationship with basic particle properties.

From the applications viewpoint, chemical analyses of aquatic sediments are essential in the assessment of their contaminant loadings, in reconstructing the history of contaminant deposition, and in quantifying the rate at which sediment–water exchange processes contribute to recovery from contamination. The bioavailability of toxins in contaminated sediments has also become a priority for managers of aquatic systems. In an attempt to assess the impact of sediment chemistry and toxicity on the health of bottom-dwelling organisms a Sediment Quality Triad has been developed.

## Sediment Sampling and Preservation

There is little point in undertaking complex chemical analyses of sediment samples if they have been significantly modified during collection or contaminated during subsequent laboratory manipulation. Thus, sediment collection, preservation, and analysis require careful preplanning and execution, as shown in the hierarchy of operations in **Figure 1**. Sediments should be obtained in such a way as to retain their natural integrity, although some disturbance and losses of the fine fraction may occur because of the application of relatively crude sampling methods. These include heavy mechanical grabs and corers that are deployed from a vessel and whose operation requires them to impact with the seabed, causing shock waves and sediment disturbance. Large volume sediment samples, typically of 1 m depth, can be obtained by a spade-box corer from which undisturbed sediment subcores can be taken by carefully inserting plastic tubes. Multicorers are used to obtain several undisturbed samples at the same site, allowing assessment of small-scale variations in sediment composition to be made, especially in areas of bioturbation or variable sediment texture. In shallow waters, *in situ* collection

**Figure 1** Hierarchy of operations when conducting a sediment survey, sample preparation, and analysis.

by divers may involve less sample alteration, although care should be taken to ensure that movements near the seabed do not cause sediment resuspension.

Oxic surface sediment samples should be transferred to a suitable container and stored in a freezer as soon as possible after collection. Suitable containers will depend on the analyte, such that sediments for metal and/or radiochemical analyses are stored in acid-washed, plastic containers. Glass or metal containers should be used when storing sediments for the analysis of organic molecules, since plastic may contain similar organic compounds that may leach into the sample. Prior to use, glass or metal containers are normally washed repeatedly in an organic solvents, such as high-performance liquid chromatography (HPLC)-grade acetone and hexane and then baked at high temperature ( $\sim 450^{\circ}\text{C}$ ) overnight.

The preservation of the integrity of subsurface anoxic sediments, normally retained in a plastic core tube, is more taxing. Immediately on retrieval, the top of the sediment core tube is enclosed within a plastic glove bag filled with an inert gas, e.g., 'white spot' nitrogen and the core is extruded from the tube by applying a piston to its base. The sample can be sectioned, into slices of appropriate thickness, as the sediment core is extruded into the nitrogen-filled glove bag. The separation of pore waters from the sediments is essential since they may contain significant concentrations of redox-sensitive elements, which, if exposed to the atmosphere, may precipitate on the sediment particles thereby modifying their composition. Isolation of the pore waters is achieved by centrifugation using sealed, plastic centrifuge tubes flushed with an inert gas. After decanting the pore water under nitrogen the centrifuge tubes containing the anoxic sediments are stored in a freezer.

## Determination of Sediment Properties

The concentrations of adsorbed sedimentary constituents tend to increase with decreases in particle diameter owing to an enhancement of the surface area per unit weight. To account for regional diversity of sediment grain size distributions, separation of a fine fraction is undertaken by sieving through a mesh (grain size commonly  $< 63\ \mu\text{m}$ ) of plastic or metal, appropriate to the analyte. However, the fine fraction may form only a small part of the total sediment and given that sieving is time-consuming and does not always disperse aggregates, it may be preferable to carry out chemical analyses of the bulk sediments. Concentrations of the constituents can be normalized with respect to a property of the fine fraction, such as percentage weight, specific surface area (via BET nitrogen adsorption on a freeze-dried sample), or by reference to the total concentration of a major

element, such as Al or Li. The grain sizes of cohesive muds can be obtained from sedimentation tubes, generally known as Owen Tubes, or by laser granulometry (operating in the range  $2\text{--}1000\ \mu\text{m}$ ). High-resolution scanning and transmission electron microscopy yield details of particle morphology, including size and shape. If the instrument is fitted with an element dispersive X-ray analyzer, major elements (Al, Ca, Si, Fe) can be determined, thereby identifying differences in the detrital (i.e., the underlying solid phase) composition of individual particles as a function of particle size. Where mineral phases have been separated on the basis of density or magnetic properties, their mineralogy can be examined by X-ray diffraction methods.

The surfaces of sediment particles normally have deposits of natural organic macromolecules, such as humic and fulvic acids, and ferromanganese oxides. The organic macromolecules have functional groups that are effective sorbents for persistent organic pollutants and, together with the oxides, they are sites where metals undergo surface complexation reactions. The proton and cation exchange capacities of natural sediments have been obtained from acid-base titrations. Extraction of surface-bound humic (molecular weight  $\sim 10\,000\ \text{Da}$ ) and fulvic ( $< 5\,000\ \text{Da}$ ) compounds can be made using sodium hydroxide. The extracts can be concentrated on a resin column, separated by liquid chromatography, and detected by ultraviolet (UV) spectrophotometry or Fourier transform infrared spectrophotometry or by gas chromatography-mass spectrometry (GC-MS). Total carbon, hydrogen, nitrogen, and sulfur analyses are undertaken by using a commercially available combustometric technique and particulate organic carbon can be similarly determined after removal of inorganic carbon by acidification. Isotope ratio-mass spectrometry (IRMS) has been used to determine the mean  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  in sediments:

$$\delta^{13}\text{C} = [((^{13}\text{C}/^{12}\text{C})_{\text{sample}}/(^{13}\text{C}/^{12}\text{C})_{\text{PDB}}) - 1] \times 1000$$

$$\delta^{15}\text{N} = [((^{15}\text{N}/^{14}\text{N})_{\text{sample}}/(^{15}\text{N}/^{14}\text{N})_{\text{air}}) - 1] \times 1000$$

The equations give  $\delta^{13}\text{C}$  values (per mil or per thousand) using Chicago PDB carbonate as the standard and  $\delta^{15}\text{N}$  values (per mil or per thousand) with atmospheric nitrogen as the standard value. The  $\delta^{13}\text{C}$  values for individual compounds, albeit with some loss of sensitivity, can be determined by coupling IRMS with GC separation of sediment extracts. The combination of C:N ratios and  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  values give vital information on the provenance of sediments since the values are significantly different for various particle types (Table 1). The determination of

**Table 1** Examples of C:N ratios and  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  values for various particle types

$^{18}\text{O}/^{16}\text{O}$  and deuterium/hydrogen ratios in sedimentary organic matter could be of advantage to paleolimnological studies concerned with the reconstruction of paleoclimate. However, there are considerable practical difficulties in the analysis of these stable isotopes and few laboratories currently have the required level of analytical skills.

## Chemical Analyses of Sediments

The determination of trace constituents in sediments requires that contamination be minimized during sample manipulation, which should be conducted in a clean room, or, at least, in a laminar flow hood. The laboratory-ware should be of good-quality borosilicate glass, polyethylene, or Teflon and high-purity reagents be used throughout to reduce the blanks. Normally, the analysis of sedimentary constituents involves a freeze-dried or air-dried sample that can be accurately weighed. If appropriate, samples may be homogenized by mortar and pestle and then sieved. Drying and chemical treatment of anoxic sediments should be undertaken in an inert atmosphere and with reagents that are oxygen-free.

## Metals

The analysis of metals by X-ray fluorescence has been widely used on geological and sediment samples, either deposited on filters or as thin films. The method can be made quantitative by using geological standards and transition metals can be determined in the 1–5  $\mu\text{g/g}$  range. The surfaces of sediment particles can be examined by the direct use of electron microprobe X-ray emission spectrometry and Auger electron spectroscopy. Although these methods are not particularly sensitive, they can allow the determination of a depth-profile of trace metals within a sediment particle.

Determinations of total metals in sediments can be achieved with electrothermal atomic absorption

spectrometry or multielement inductively coupled plasma-mass spectrometry (ICP-MS), following microwave assisted extraction (MAE) using concentrated  $\text{HNO}_3$  and HF in sealed Teflon vessels. The accuracy of the method can be verified by certified reference sediments, such as MESS-3 and PACS-2 available from the National Research Council of Canada (NRCC). High-resolution ICP-MS is also used for determinations of isotopes, for example,  $^{204}\text{Pb}$ ,  $^{206}\text{Pb}$ ,  $^{207}\text{Pb}$ , and  $^{208}\text{Pb}$  in studies of source apportionment. Direct analysis of solid samples may be possible and has a number of advantages, including reducing the preparation time, minimizing contamination, retention of volatile elements, and determination of highly refractory matrix-bound elements. Methods involve slurry nebulization ICP-MS using finely ground, fluidized sediments and laser ablation ICP-MS where solid samples are mixed with a binder and pelletized. Determinations of total metals allow geochemical normalization using concentrations of Al, since it is a major component of aluminosilicate minerals and it is usually unaffected by anthropogenic inputs. However, Li is a potentially superior normalizer because, unlike Al, it is not usually present in feldspars. An added advantage of geochemical normalization is that it allows estimation of enrichment factors.

Metals associated with various binding sites on sediments have been assessed using extraction procedures applied as single digests or as a set of sequential steps. Selective dissolution of trace metals from the particle surfaces is followed by determination using atomic absorption spectrometry (AAS), ICP-MS, or total reflection X-ray fluorescence. The use of sequential extraction schemes for the operational definition of metal species in sediments has proved contentious. They have been criticized on the basis that the reactions are not sufficiently phase selective and labile phases could be transformed during sample preparation, causing a marked reduction

**Table 2** A sequential extraction scheme for trace metal speciation in sediments. The first three steps relate to the standardized sequential extraction method applicable to BCR CRM 601

Fraction	Extractant	Extracted component
Exchangeable and carbonatic	0.11 mol l <sup>-1</sup> HOAc	Exchangeable ions and carbonates

in selectivity, particularly for anoxic sediments. Moreover, until recently there was no appropriate certified reference material (CRM), allowing international comparison of data. The Community Bureau of Reference (BCR, now renamed as the Standards, Measurements and Testing Programme) of the European Union has produced sediment reference material CRM 601 which can be used in the validation of a three-stage sequential extraction procedure (Table 2). In the case of anoxic sediments, methods have been developed for determination of acid volatile sulfides simultaneously with the extraction of metals, under oxygen-free conditions. This combined approach is useful in interpreting the data from bioassay tests of metal toxicants on aquatic sediments.

Innovative methods to determine the bioavailability of trace metal in estuarine sediments have been developed recently using digests that are more representative of the digestive fluids of aquatic organisms. Studies with trypsin and pepsin (two of the most important enzymes involved in the digestion of food by marine organisms) and the intestinal fluids extracted from codfish have shown significant variation from mineral reagents used in sediment extractions. Figure 2 shows the proportions of Cu and Zn released by single extractions by various reagents, relative to the concentration of total metal on estuarine sediments. Compared to Zn, Cu is associated with particulate organic material as shown by the amount released by the NaOH digest. Pepsin removed more Zn than Cu, whereas the gut fluids (1 and 2) solubilized more Cu and Zn than the enzymes pepsin and trypsin. It appears that acetic acid represents the best reagent with which to define the metals that are available under gastrointestinal conditions. However, more research is required on the extraction efficiency of other enzymes, such as proteinase-K, which targets metals associated with proteinaceous material on sediments.

Butylated Sn compounds have been determined in sediments by exploiting microwave technology to simultaneously extract and derivatize Sn compounds

**Figure 2** Percentage metal extracted, relative to the total concentration, from marine sediments by different reagents, enzymes, and the gut fluid from cod. HCl = 1 mol l<sup>-1</sup> HCl; HOAc = 25% glacial acetic acid; NaOH = 0.1 mol l<sup>-1</sup> NaOH; Pepsin = Pepsin a pH 2; Trypsin = Trypsin II-S pH 7.6; Gut fluid (1) = natural filtered intestinal fluid, pH 7; Gut fluid (2) = natural filtered intestinal fluid, pH 2. (A) Cu and (B) Zn. (usually by ethylation) to give volatile tetra-substituted species, suitable for separation by GC. Methyl mercury species have been released from sediments by using KOH/methanol mixtures in sealed Teflon

reactors with an open focused MAE system. Subsequently, the methylated Hg species are extracted into a suitable organic solvent, separated by HPLC and the individual methylated compounds decomposed by UV irradiation as they come off the column. The pulses of inorganic Hg are then detected by cold vapor-atomic fluorescence spectrometry. The accuracy of analytical methods for Sn and Hg can be verified with certified reference sediments for mono-, di-, and tributyl tin (BCR CRM 646) and for methyl mercury (BCR CRM 580). Arsenic species on sediments (including the methylated forms) have been determined by coupled HPLC-ICP-MS following their extraction in phosphoric acid using a low-power MAE system.

### Radionuclides

Radionuclides such as  $^{238}\text{Pu}$ ,  $^{234}\text{U}$ , and  $^{232}\text{Th}$  emit  $\alpha$ -particles that have a limited penetration in matter, requiring a complex separation and preconcentration of the individual elements from sediments. Alpha-emitting radionuclides can be separated from sediments by a primary digestion with concentrated mineral acids (e.g., aqua regia) followed by several steps involving precipitation and ion exchange. Chemical yields for the various elements can be obtained using internal spikes that are not present in natural sediments (e.g.,  $^{236}\text{Pu}$ ) and the accuracy of the analyses can be verified with CRMs, such as International Atomic Energy Agency (IAEA)-367 sediment for  $^{239(240)}\text{Pu}$ . Thin sources are prepared, for example, by electrodeposition or by microprecipitation with  $\text{NdF}_3$  onto polyethylene filters (pore size  $0.1\ \mu\text{m}$ ), prior to  $\alpha$ -spectrometry, using silicon surface barrier detectors coupled with pulse height analysis by a multichannel analyzer. More progress has been made in the use of nonradiometric methods for  $\alpha$ -emitting radionuclides at natural concentrations (e.g.,  $^{232}\text{Th}$ ,  $^{235}\text{U}$ ,  $^{239}\text{Pu}$ ,  $^{240}\text{Pu}$ ) using acid digests of sediments followed by ICP-MS determination.

Pure  $\beta$ -emitters such as tritium ( $^3\text{H}$ ),  $^{14}\text{C}$  (radio-carbon widely used in geochronology),  $^{35}\text{S}$ ,  $^{63}\text{Ni}$ , and

$^{90}\text{Sr}$  are chemically separated from the sediments before liquid scintillation counting. Tritiated molecules and  $^{14}\text{C}$  compounds have been separated from freeze-dried sediment samples using a computer-controlled, combustion technique with a  $\text{CuO}$  catalyst. The radioactive gases,  $^{14}\text{CO}_2$  and  $^3\text{HHO}$ , are separated by selective trapping and each isotope is determined by liquid scintillation counting. Limits of detection for a 20 g sample are  $\sim 20\ \text{mBq g}^{-1}$  for both isotopes. Activity concentrations for  $\beta$ -emitters can be determined, using thin sources with a  $^{40}\text{K}$  standard, or for solutions via a liquid scintillation counter or for low levels using a gas-flow multicounter.

Gamma rays from some radionuclides, such as  $^{137}\text{Cs}$ ,  $^{241}\text{Am}$ , and  $^{106}\text{Ru}$ , have a specific energy that can be detected by nondestructive gamma spectrometry using sensitive hyper-pure germanium detectors, with relative efficiencies of 20–25%. The homogenized, freeze-dried sediment is normally placed in a Marinelli beaker, shaped to surround the detector, and of 0.8 l capacity. Sediment geochronology may be determined from the gamma emission of  $^{210}\text{Pb}$  (half-life 22 years) and  $^{226}\text{Ra}$ , from which the excess  $^{210}\text{Pb}$  can be calculated and the sediments dated. Dating of sediment cores is also assisted by peaks in the activity concentration of  $^{137}\text{Cs}$ , e.g., the peak generated by deposition from the Chernobyl accident in 1986. The gamma-emitters  $^7\text{Be}$  (half-life 53 days) and  $^{234}\text{Th}$  (half-life 24 days) are both particle-reactive and, since they have different source functions, they can be applied to the tracing of sediment migration in estuaries.

Activity concentrations for various gamma-emitting radionuclides in coastal marine sediments from the Irish sea are given in Table 3. A major source of radionuclides to the Irish Sea is the Sellafield nuclear reprocessing plant and the distribution of radionuclides shows that higher concentrations may be found away from the source, thereby emphasizing the point concerning particle properties because the higher activity concentrations are associated with the finer sediments either side of the source.

**Table 3** Mean activity concentrations<sup>a</sup> of gamma-emitting radionuclides in sediments from the coastal region of Cumbria, UK

Location	Sediment type	Activity concentrations ( $\text{Bq kg}^{-1}$ )			
		$^{241}\text{Am}$	$^{60}\text{Co}$	$^{137}\text{Cs}$	$^{106}\text{Ru}$
St. Bees	Sand	180	4.5	87	<4.0
Sellafield	Sand	230	5.2	90	<4.6
Ravenglass	Mud	1500	64	610	190
Ravenglass	Mud and sand	500	26	210	51

## Organic Compounds

**Polychlorinated organic compounds** Polychlorinated biphenyls (PCBs) comprise a family of 209 individual compounds, referred to as congeners, and to make identification easier systematic numbering was introduced by the International Union for Pure and Applied Chemistry (IUPAC). For example, toxicologically important PCB congeners notably 3,3,4,4'-tetrachlorobiphenyl, 2,3,3',4,4'-pentachlorobiphenyl, and 3,3',4,4',5-pentachlorobiphenyl have the IUPAC numbers 77, 105, and 126, respectively. Polychlorinated dibenzodioxins (PCDDs) have 75 congeners and polychlorinated dibenzofurans (PCDFs) have 135 congeners, although there is no numbering system. PCBs and PCDDs/PCDFs are found at low concentrations in sediments (in the range ng per g to pg per g) and co-contaminants have to be eliminated from the samples prior to analysis, which requires considerable analytical expertise to identify the compounds on a congener-specific basis.

Due to the wide range of organic compounds in sediments, a three-stage analytical protocol is generally adopted:

1. Extraction of the organic compounds from a dried sediment sample: Prior to extraction an internal standard mixture of  $^{13}\text{C}$ -labeled compounds is added to the sediments. The extraction is normally carried out in a Soxhlet apparatus with an azeotropic mixture of organic solvents such as hexane and acetone or benzene and toluene. The extract is then concentrated using rotary evaporation and dried if appropriate.
2. Cleanup of the extract: This step involves the removal of other organic components that have been coextracted in stage (1) and would interfere with subsequent analyses. This stage is usually carried out by using column chromatography, thereby allowing the various homologs to be eluted and separated. This process may need to be repeated on an iterative basis to ensure complete removal of interfering compounds.
3. Separation, identification, and quantification: Using GC-MS with internal quantification standards that are added as spikes at the extraction stage. If the subsequent GC-MS analyses reveal that accurate determination of PCDDs and PCDFs is not possible owing to the presence of interfering peaks then liquid chromatography separation may be employed.

Developments in high-resolution GC and/or MS allow the detection of ultralow concentrations,  $\sim 10^{-15}$  g, on-column. However, any increased sensitivity brings additional problems and emphasizes the need to control contamination in reagents and glassware. Considerable improvements have been made in the precise quantification of many

compounds by isotope dilution-MS because of the availability of a wider range of  $^{13}\text{C}$  and deuterated compounds of organic molecules. Advances are being made in the coupling of instrumental techniques such as HPLC with MS, which will yield a highly sensitive method for the detection and quantification of more polar and water-soluble compounds. A novel approach to the determination of broad classes of chlorine-, bromine-, and iodine-containing organic compounds in sediments, extracted into a mixture of methylene chloride and hexane, involves monitoring the gamma-ray emissions of  $^{38}\text{Cl}$ ,  $^{80}\text{Br}$ , and  $^{128}\text{I}$ , following neutron activation of the extracts.

Determinations of polyaromatic hydrocarbons (PAHs) in freeze-dried sediments (sample mass of the order 10–20 g) has been carried out where hexamethylbenzene added as a standard to the sediment prior to extraction. The sediments were extracted sequentially with methanol followed by methylene chloride and substituted and unsubstituted were determined by GC-MS. The accuracy of the method was verified using the marine reference material HS6 (NRCC). The technique allowed the determination of 17 unsubstituted and 33 substituted PAHs with detection limits in the range 50–200 ng per g. An example of the results from the sediment core from a Canadian fjord contaminated with PAHs derived from an aluminum smelter is shown in Figure 3. The PAH concentration illustrates the wide concentration range available to this analytical method and also show the variation of PAH concentrations with depth. Each PAH has an increase in concentrations

**Figure 3** Concentrations of PAHs in a sediment core from Kitimat Arm, Douglas Channel, British Columbia.  $\circ$  – total unsubstituted PAHs;  $\blacktriangle$  – unsubstituted perylene;  $\square$  – phenanthrene;  $\times$  – fluoranthrene;  $\diamond$  – 2-methylphenanthrene. (Adapted from Simpson CD, Harrington CF, Cullen WR, Bright DA, and Reimer KJ (1998) Polycyclic aromatic hydrocarbon contamination in marine sediments near Kitimat, British Columbia. *Environmental Science and Technology* 32: 3266–3272.)

between 20 and 45 cm depth, indicating the beginning of Al smelting.

Surfactant compounds that sorb onto sediments after discharge from sewage works are thought to be endocrine disrupters and are, therefore, of considerable interest to environmental managers. One of the largest classes of commercially available nonionic surfactants are the nonyl phenol-*n*-ethoxylates defined by the abbreviation Np*n*EO, where *n* is the number of ethoxylate groups that normally reach a maximum of 9, giving rise to a large number of isomers. Biodegradation of Np*n*EOs takes place during sewage treatment and the more lipophilic and persistent alkylphenols are formed. Current methods involve the extraction of freeze-dried sediments, ground to a free-flowing powder, with hexane/acetone mixtures, using an accelerated solvent extraction system where the sample is held at 100°C and 1500 psi. After the extract is reduced to dryness, it is reconstituted with hexane and the extract cleaned up on a solid-phase extraction cartridge. The final extracts can be analyzed by coupled normal liquid phase chromatography–electrospray mass spectrometry. Detection limits are in the low ng per g range. Shang *et al.* in 1999 found that the average concentrations for total NpEO in the sediments of the Straits of Georgia, Canada were 1500 ± 130 ng per g; whereas in the Venice Lagoon the range was 500–6700 ng per g (total of Np, Np1EO, and Np2EO), and in marine sediments near a Barcelona sewage outfall the range was 100–6600 ng per g. Concentrations of the breakdown product octylphenol were typically <20 ng per g.

## Soil, Major Inorganic Components

**H van der Jagt**, KIWA Water Research, Nieuwegein, The Netherlands

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Major inorganic compounds, such as trace elements, are of concern as contaminants of terrestrial and

aquatic systems because of their persistence and toxicity at low concentrations. There is considerable evidence that the bioavailability and toxicity of such trace elements are markedly influenced by the physicochemical forms in which they are present in waters, in sediments, and in soils. Specifically, concerns about trace elements relate to utilization, disposal, and discharge of sewage and wastes. With regard to aquatic systems, complexation reduces the toxicity of

dissolved trace elements to a range of aquatic organisms and trace element uptake and toxicity often relate best to the free metal ion activity. In general, systematic differences in the geochemistry of groundwater evaluation in aquifers are traceable to local solid variability. For instance, variations in Sr isotopes and Mg/Ca and Sr/Ca ratios offer insight into the influence of soils on groundwater geochemistry, sources of dissolved constituents in groundwater, water-rock interaction pathways, and groundwater residence time.

The chemical composition of water in relation to the Earth's crust constitutes the focus of the science called geohydrochemistry or simply geochemistry. Water quality is one of the primordial environmental factors determining which flora and fauna will thrive and which material will dissolve or precipitate. Environmental research helps gain insight into aspects such as economics, sensitivity, and relevance in pollution studies: economics for the possibility of cost-effective direct measurement without complicated extractions prior to analysis, sensitivity because of an analytically more agreeable result when compared to the solid phases in soil, and relevant on account of a direct selection of the mobile phases.

## Geochemistry of Soil

The main objectives of the geochemistry of soil are based on the aids required in the solution of specific hydrological problems, e.g., the determination of the origin of groundwater by recognition through specific natural tracers and visualization of actual patterns by mapping groundwater of various origins and characteristics. Geological formations, soil classes, or flow systems are discerned on the basis of their genesis.

### Scientific Issues

Experiments during artificial recharge are ideal for comparison between laboratory experiments and field studies. They unify the advantages of both: most experimental conditions are well defined, the scale of operation is large enough to contain the natural heterogeneity, and the timescale is also sufficient for the detection of specific trends. The scientific issues involved are generally studying the kinetics of denitrification, pyrite oxidation, the oxidation of organic matter, and the quantification of the reactive fraction of organic matter and of the trace element content of pyrite.

The main processes in soils demonstrate oxic influents (rainwater, surface water) and anoxic soil containing pyrite resulting in mean order of increasing duration: displacement of native groundwater, cation exchange, pyrite oxidation, acid buffering by

calcite dissolution, and oxidation of organic matter. Differences in quality changes between different sites relate to their deviating aquifer geochemistry and influent quality.

## Geochemical Monitoring

Water quality monitoring consists of frequent analysis of the main constituents. The required data input consists of: (1) mean composition of the influent; (2) mean composition of native groundwater in each layer of the target aquifer; (3) native geochemistry of each layer of the target aquifer; (4) the cumulative frequency curve of detention times in each model layer or flow path as derived from either separately run hydrological model or tracer breakthrough data; and (5) specific information derived from the mass balance of the water phase (the reactions that are needed, how  $O_2$  and  $NO_3^-$  distribute over the various redox reactions, etc.).

The results demonstrate the following effects: (1) displacement of the native groundwater by the influent, including effects of dispersion; (2) leaching of reactive aquifer constituents: exchangeable cations, calcite, organic matter iron sulfides and  $MnO_2$ ; and (3) breakdown of organic micropollutants.

With regard to chemical reactions, target aquifer samples have been determined to give information on grain size distribution and porosity, and quantitative chemical analysis for total element content (by X-ray fluorescence (XRF)), iron sulfides, calcium carbonate, exchangeable cations, organic matter, and organic carbon.

## Geochemical Composition

The main chemical composition of an aquifer is deep anoxic, mainly quartz sand, poor in organic carbon, containing a small amount of pyrite and calcite. Cation-exchange capacity (CEC) is low, dominated by  $Ca^{2+}$  and  $Mg^{2+}$ . The top of the layer contains more organic carbon, calcite, and pyrite.

### Organic Compounds

Due to variations in the soil, such as humic constituents, sand fractions, clay minerals, peat minerals, wood rests, algal toxins, and deposits of shell lime, different reactions take place. The natural organic matter (NOM) in an aquifer is a complex mixture of substances, such as humic acids, fulvic acids, amino acids, carbohydrates, lipids, lignin, and waxes.

Dissolved organic carbon and color become progressively reduced upon aquifer passage probably by degradation in presence of oxygen, nitrate,

and sulfate (organic compounds react in these cases like a redox buffer). Oxidation of organic compounds leads to dissolving of organic compounds (fulvic acid, dissolved organic carbon, inorganic carbon and nutrients, iodide, nitrogen, hydrogen sulfide, and methane). The reactions are important with regard to strong absorbent working formations.

### **Carbonate Minerals**

Calcium carbonate (such as calcite, siderite, dolomite, and aragonite) is typically present in marine deposits and Pleistocene sediments deposited in riverbanks and practically absent in deposits from ancient rivers and deposits of Miocene age. Calcium is generally the dominant exchangeable cation (56–82%) followed by magnesium (6–26%). An important parameter for behavior during aquifer transport is the calcite saturation index ( $SI_c = \log[Ca^{2+}][CO_3^{2-}]/K_{CaCO_3}$ ).

### **Sulfide Minerals**

The geochemical heterogeneity of the aquifer mainly consists of a higher reactivity of pyrite and elementary sulfur in the lower zone and a higher reactivity of organic matter in the upper parts. Pyrite oxidation is relatively fast in the presence of oxygen and nitrate (reaction nitrate in nitrogen). During the oxidation of pyrite elemental sulfur, sulfate, iron, and trace elements (heavy metals) will be mobilized.

### **Hydroxide Minerals**

The presence of iron hydroxides, manganese oxides, and aluminum hydroxides (gibbsite and jurbanite) in soils will be mobilized under anoxic or acid ( $pH < 5$ ) environmental conditions.

### **Clay Minerals**

Illite is the most dominant mineral present in soil samples. Apart from this mineral even smectite, kaolite, and chlorite will be present in the soil. Illite absorbs, in practice, some potassium, ammonium, cesium, and rubidium species. The solubility of clay mineral is quite high under acidic ( $pH < 4$ ) environmental conditions.

## **General Overview of Analytical Techniques**

In this overview, techniques highlighted are those that, based on our experience, represent current trends and state-of-the-art technologies in elementary analysis, and specific extractions in real environmental samples. Also reviewed are relatively new analyses of interest and detections that are made possible by recently developed analytical methods.

### **Elemental Analysis**

This technique comprises a group of quantitative analytical methods. Iron, carbon, and calcium will be determined. It is necessary to use strong techniques such as microwave to digest the soil samples completely. The whole soil sample will not be completely reactive in all cases, only a part will be reactive.

### **Selective Extractions**

The main reason for determining a specific constituent like calcite, organic carbon, and pyrite or a selective bounding form of elements is the necessity to perform selective extractions. Solid-phase extraction of (in)organic compounds continues to be the leading technology for the exhaustive extraction of selective compounds from soil samples.

### **Sequential Extractions**

The solubility of the specified constituent can be determined by sequential (step by step) extractions. An advantage of these step-by-step performances is the availability of information on individual groups of oxides, carbonates, sulfides, and silicates. One disadvantage is the high cost involved.

### **Other Techniques (Mostly Semiquantitative)**

Nuclear magnetic resonance spectroscopy has emerged as a powerful technique to explore analyte–matrix interactions. Another powerful technique is scanning electron microscopy, which provides details on morphology and mineral variations of the soil. The resolution is at a microlevel ( $\pm 5 \mu m$ ).

Complex reactive transport models are integrated with geophysical information systems applied to radionuclides. The behavior of  $^{90}Sr$ ,  $^{60}Co$ ,  $^{106}Ru$ , and  $^{137}Cs$  can be used for breakthrough purposes. Short pulses (of 1–28 days) with 100% activity can be chosen as input signal in order to simulate a calamity at the recharge facilities.

## **Geochemical Analyses**

Most studies were inspired by questions regarding the fate of pollutants upon detection in spreading basins and upon passage of aquifer systems, before recollection, post-treatment, and distribution as drinking water.

Since there already exist several review articles, highlights of the most important methods and comments on the different principles will be described. Variations in performing analytical methods especially for calcite, organic carbon, pyrite, sulfides, and CEC reaction have resulted in the development of standard methods. In **Figures 1–4**, the most common analytical

methods are described with linking pins to their comprehensive approaches based on numerous trends.

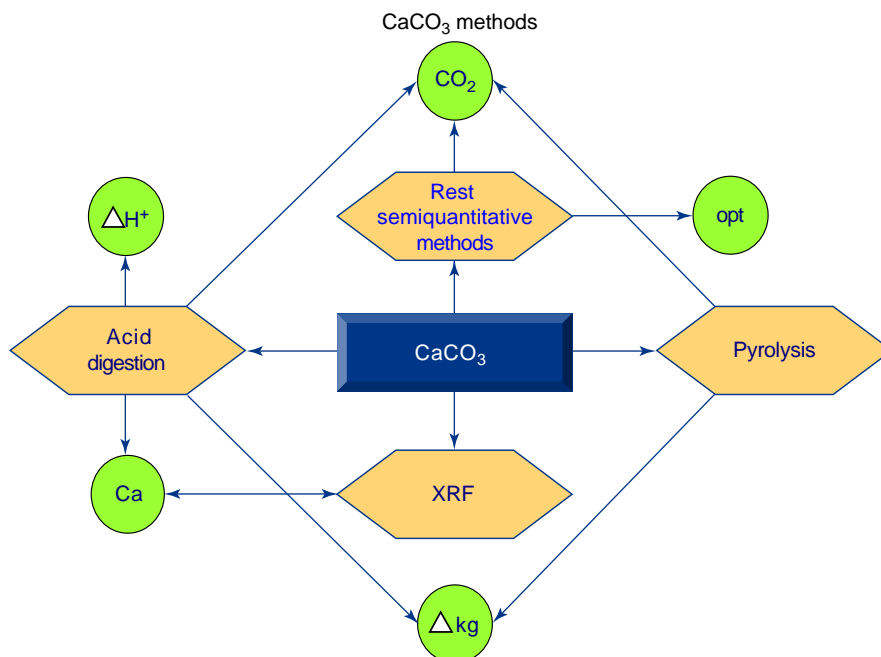

### Calcium Carbonate (Calcite)

Quantitation provides the highest accuracy level achievable by  $\text{CaCO}_3$  methods. The digestion of calcium carbonate can be determined in four different ways: (1) digestion with acid; (2) thermal gravimetric analysis (TGA at  $105^\circ\text{C}$ ,  $450^\circ\text{C}$ ,  $550^\circ\text{C}$ , and  $1000^\circ\text{C}$

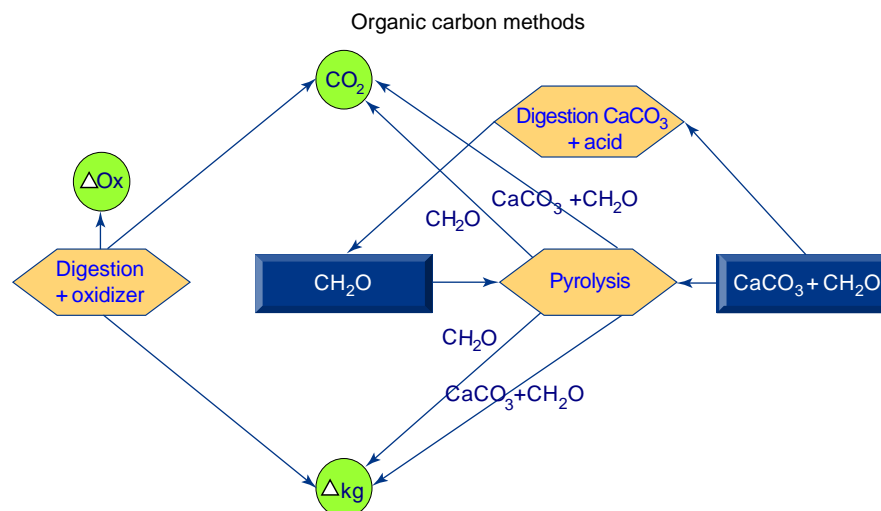

on bulk organic material); (3) XRF; and (4) semiquantitative methods (granular, or ion-exchange complex and CEC, or  $\text{CO}_2$  pyrolysis with acid addition). In some cases, postanalysis calculations correct overestimation for the presence of exchangeable calcium.

### Organic Carbon

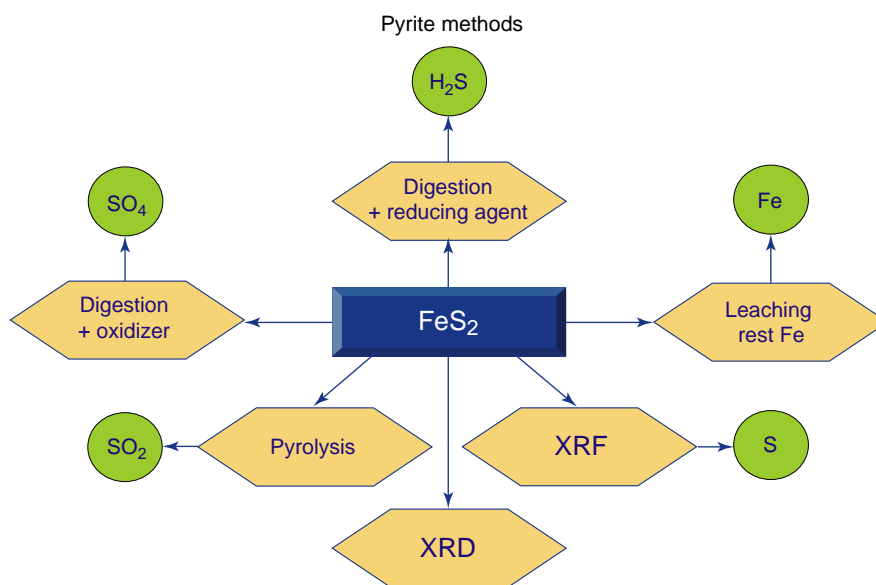

Sorbing and oxidizing solutes are retarded during aquifer passage and similarly desorbing and dissolving

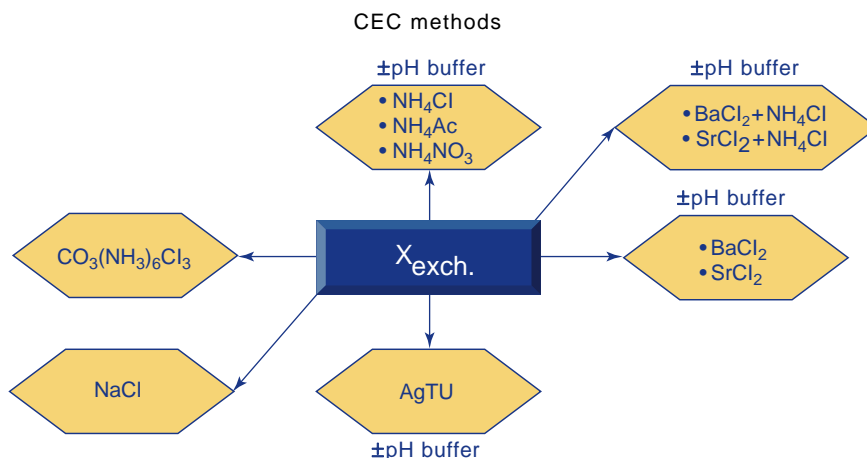

**Figure 1** Five analytical methods for the determination of calcite in soil with specific types of digestion. In the circle is a declaration of the analytical parameter ( $\Delta\text{H}^+$  = concentration of used acid,  $\Delta\text{kg}$  = decrease of weight). The hexagons contain the method of digestion. XRF = X-ray fluorescence.

**Figure 2** Three analytical methods for the determination of organic carbon in soil with specific types of digestion. In the circle is a declaration of the analytical parameter ( $\Delta\text{Ox}$  = concentration of used oxidation, e.g., hydrogen peroxide or  $\text{K}_2\text{Cr}_2\text{O}_7$ ,  $\Delta\text{kg}$  = decrease of weight). The hexagons contain the method of digestion.

**Figure 3** Six analytical methods for the determination of pyrite ( $\text{FeS}_2$ ) in soil with specific types of digestion. In the circle is a declaration of the analytical parameter. The hexagons contain the method of digestion. XRD = Roentgen diffraction, XRF = X-ray fluorescence.

**Figure 4** Five analytical methods for the determination of exchange cation salts for the determination of exchange cations and the CEC in soil. The hexagons contain the method of cation exchange.

compounds are delayed by leaching. The leaching of organic matter is generally the result of oxidation by  $\text{O}_2$  and/or  $\text{NO}_3^-$ . After leaching of the easy degradable (labile) fraction of organic matter (sometimes 2%), the tough fraction is to be leached. About 20% is considered inert then. The highest accuracy level of organic carbon dating methods can be approved by quantitation. The digestion of organic carbon can be determined in three different ways: (1) TGA ( $105^\circ\text{C}$ ,  $450^\circ\text{C}$ ,  $550^\circ\text{C}$ , and  $1000^\circ\text{C}$  on bulk organic material); (2) digestion of  $\text{CaCO}_3$  with acid after which pyrolysis is conducted; and (3) digestion with an oxidizer. In some cases, postanalysis

calculations correct the overestimation for the presence of lutum (particles  $<2\ \mu\text{m}$ ) and free iron with bounded water crystals.

### Sulfur and Iron Sulfides (Pyrite)

Pyrite oxidation can be considered as the most important water-sediment reaction. Using kinetic methods, this reaction proved to be relatively a slow process, as the oxidation of pyrite takes  $\sim 10$ – $100$  days to deplete  $\text{O}_2$  and  $\text{NO}_3$  into the water phase. The progress of the reaction is the observation of an increase of sulfate ( $\text{SO}_4$ ). It appears to be that

oxygen is reacting faster with pyrite than with labile NOM and that the reverse holds for nitrate. The oxidation of pyrite leads to some mobilization of As, Co, and Ni.

Multivariate techniques can define structure in providing the highest accuracy level achievable by analytical methods for mono- and disulfides (pyrite). Pyrite ( $\text{FeS}_2$ ) can be determined in eight different ways: (1) digestion of sulfate with an oxidizer (hydrogen peroxide, aqua regia, or concentrated  $\text{HNO}_3$ ); (2)  $\text{SO}_2$  pyrolysis according to Strohlein CS-5500; (3)  $\text{SO}_2$  pyrolysis, correction on carbonates with acid; (4) digestion with reducing agent; (5)  $\text{SO}_4$  in silver thio-ureum (AgTU) extract (with and without ammonium acetate) by CEC determination; (6)  $\text{SO}_4$  sum by sequential extractions, differentiation of sulfur constituents; (7) XRF; and (8) Röntgen diffraction (XRD) semiquantitative methods (granular, or ion-exchange complex and CEC, or  $\text{CO}_2$ -pyrolysis with acid addition). Postanalysis of geochemical data utilizing robust statistical information accounts for the sum of elemental sulfur, monosulfides, and disulfides as a result of the two-way sequential extractions. In most cases, inductively coupled plasma mass spectrometry (ICP-MS) and ion chromatography (IC) are used because of their low detection limits and analytical behavior in complex salt matrices.

### Cation-Exchange Capacity

Generalized evaluation of quality changes of an oxic aquifer evolves in a specific way with time due to sequential leaching of reactive components of the aquifer matrix. The evaluation reveals the following phases: displacement, exchange reactions, redox reactions,  $\text{NO}_2$  breaking through, leaching of pyrite and calcite. Exchange and sorption reactions between influent and aquifer matrix dominate during the quality changes. While most methods reviewed are instrument based, wet chemical techniques are also used.

Some multivariate techniques (Figure 4) can be used to define structure in providing the highest accuracy level achievable by analytical methods for CEC: exchange of cations in strontium chloride ( $\text{SrCl}_2$ ) or a combination of  $\text{SrCl}_2$  + ammonium chloride ( $\text{NH}_4\text{Cl}$ ), pH 7.6; determination of CEC with silver thio-ureum (AgTU) extract (with and without ammonium acetate) by CEC determination; and exchange of cations with salt solutions ( $\text{NaCl}$ ).

Postanalysis of geochemical data involves robust calculations to account for the total exchange capacity for cations as a result of the cation exchanges. In most cases, ICP-MS and IC are performed in the final extracts due to its low detection limit capacity and their analytical behavior in complex salt matrices.

## Analytical Techniques

This article surveys brief information according to the analytical techniques used for determining terrestrial samples.

### Laser Particle Sizer

This technique claims a working range of 0.16–1250  $\mu\text{m}$ . All particles give diffraction in all directions. Thus, light scattered by particles outside the measured range affects the results over that measured range. The suspension is pumped through a sample cell placed in the convergent laser beam and the forward-scattered light falls on 31 photosensitive sensor rings. The particle size distributions from the diffraction patterns measured by the laser are calculated using the Chahine inversion scheme.

### Atomic Spectrometry

This technique comprises a group of quantitative instrumental analytical methods based on the capacity of free atoms of both emitting and absorbing radiation at a specific wavelength. The radiation lies within the range for ultraviolet and visible light. A distinction is made between atomic emission spectrometry (AES), atomic absorption spectrometry (AAS), and atomic fluorescence spectrometry. The most commonly applied techniques are flame-AAS, graphite furnace-AAS, and ICP-AES. With ICP, excitation takes place in a plasma at a temperature of  $\sim 7000\text{ K}$ .

The best-known technique based on a combination of methods is ICP-MS. Here, the excited atoms are introduced upon their return to a lower energy level, through an interface into the ion source of a quadrupole of a mass spectrometer. The ICP thus acts as an ion source and the mass spectrometer as the ion detector. The latest development in atomic spectrometry is the electrothermal evaporation-ICP-MS technique, where a graphite furnace is coupled to an ICP-MS. In this case, use is made of the most remarkable property of a graphite furnace (elimination of matrix interferences) by a graphite tube atomizer and subsequent transport of the atomic phase into the plasma and quadrupole.

### Instrumental Neutron Activation Analysis

In instrumental neutron activation analysis (INAA), following the activation of a soil sample, preconcentrated or otherwise, by radiation with neutrons, photons (gamma radiation), or charged particles, the radioactivity generated is measured by sensing the entire gamma spectrum with a semiconductor

detector. The most commonly applied variant is epithermal neutron activation analysis.

### **X-Ray Fluorescence**

Soil is bombarded with X-rays when electrons are ejected from the innermost shells of the atoms. When the hole made in the electron shell is refilled, X-rays are emitted at a longer wavelength than the radiation previously absorbed. This wavelength is characteristic for each kind of atom so that measurement of the whole spectrum provides an analysis of the chemical proposition. XRF is a well-established analytical method for determination of major and minor elements in geological materials.

### **Ion Chromatography**

A major development is the determination of trace levels of anions in digested soil samples in a closed system using microwave-assisted heating. A specific conductometric method combines the quantification of anions by IC with specific dilution steps, which mainly comprises a selective de-enrichment of all water solution constituents.

### **Combined Methods**

Several recent studies have used quadrupole ICP-MS in combination with laser ablation (LA-ICP-MS), liquid chromatography-ICP-MS, and/or high-resolution and multi-collector ICP-MS. Despite the fact that the advantages of high sensitivity of mass spectrometric techniques are mostly applicable to the analysis of terrestrial samples simultaneously, scanning electron microscopy demonstrates the performance characteristics of inclusions in minerals and generally agrees well with published values.

## **The Mass Balance Approach**

The mass balance approach demonstrates both reactive solutes in the water recharged and solid reactive phases in the aquifer system. Some empirical rules regarding the sequence of reactions, reaction kinetics, and mobility of elements completes the dynamic quality changes of an infiltrating solute, which leaches the aquifer. Chemometric data analysis techniques allow geoanalytical chemists to control the quality of results from routine analysis by discovering trends within large multivariate datasets, and assessing and even improving data quality. Therefore, the use of multivariate quality control techniques is favored to assess data quality in routine analyses by bulk analytical techniques such as ICP-MS, XRF, and INAA. It has also been suggested that a combination of mass balance approach, principal component analysis, and

statistics could provide tools for error recognition and diagnosis. Easy-Leacher is an analytical two-dimensional spreadsheet model simulating the dynamic quality changes of an infiltrating solute, which leaches the aquifer. This mass balance approach for both reactive solutes in the water recharged and solid reactive phases in the aquifer system is combined with some empirical rules regarding the sequence of reactions, reaction kinetics, and mobility of elements. This model simulates for as many strata as desired: e.g., displacement of the native groundwater by influent, including effects of dispersion, and leaching of reactive aquifer constituents (exchangeable cations, calcite, organic matter, iron sulfides, and  $\text{MnO}_2$ ).

Information with regard to the breakthrough of solutes, the sorption, and the breakdown of organic micropollutants will be available.

## **Challenges**

Analysis of samples on soil continues to present new challenges to the analytical geochemist. In fact, the analytical trend in geochemical research is getting more compositional information from ever-smaller samples. ICP-MS with all of its hyphenated permutations continues to be the analytical method used most widely. Other trace analysis techniques are of lesser importance particularly for noteworthy studies. A second trend in geochemical research that continues to broaden during the next decade is the application of focus more specific routes in analyzing to characterize a terrestrial sample or suite of samples. This approach has long been a staple in geochemistry where samples are rare and usually small and where bulk host material is not generally plentiful. The major appeal of the multitechnique approach is that sets generally prove synergistic.

Previous hybrid hyphenated techniques and dissolution procedures have been developed and will have benefits for the future in geochemical analysis.

## Soil, Minor Inorganic Components

A C Edwards, Peterhead, Aberdeenshire, UK

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Soil presents the analyst with various technical problems with respect to the complex and variable chemical nature of its matrix (aluminosilicate – organic) and the wide range in concentration of the minor constituents that may be present. The heterogeneous distribution of minor components means that the appropriateness of collection and preparation procedures in providing a representative soil sample must be considered. Many minor components commonly present in soil are essential to biological life processes but become toxic when present in excess. Soil receives minor components from a range of anthropogenic sources and their accumulation is of direct concern for both human and general ecosystem health. The quantification of a small but highly dynamic bioavailable fraction of the total minor component present in soil represents one important topic for analytical chemistry.

Soil is composed of a heterogeneous mixture of solid, gaseous, and aqueous phases, the relative proportions of which can vary both spatially and temporally. The solid matrix consists of an intimate mixture of inorganic (primarily weathering products) and organic (products of biological decomposition) components. The proportion of total soil porosity occupied by water may vary from very low values up to 100% in a fully saturated soil. Soils typically develop a distinctive vertical zonation as a consequence of selective mineral dissolution coupled with

transport and reprecipitation of inorganic components and a decline in organic material.

A precise distinction between what constitutes a ‘major’ or ‘minor’ soil component is difficult to make. For present purposes the term ‘minor component’ is applied to situations where total concentrations are generally <100 µg per g. This may encompass more than 50 minor components many of which could be present at concentrations below 0.1% (Figure 1).

Although most of the minor components are associated with the solid phase a small but functionally significant fraction is present in the soil solution and represents the immediately bioavailable and mobile fraction. The aqueous phase is the primary medium for redistribution and transportation of soluble and particulate bound chemical species within soil. A constant state of flux, resulting in a dynamic equilibrium, exists between solid and solution phases as both respond to local situations of depletion (e.g., plant uptake) or resupply (e.g., application of sewage sludge). Apportioning between solid and solution is sensitive to the prevailing local physicochemical environment through influences of factors such as pH, redox, and electrolyte concentrations.

### Origin of Minor Components

Total amounts of minor components vary widely between soils and are often reflective of a strong geochemical influence (Table 1). Here, soil developed from Serpentine (an ultrabasic, igneous rock) is typically high for Co, Cr, and Ni with the result that even in this ‘natural state’ concentrations are greater than the EC recommended limits for soils receiving metal-containing waste materials (see Table 2). Natural background concentrations have become enhanced

### Introduction

Soil presents the analyst with various technical problems with respect to the complex and variable chemical nature of its matrix (aluminosilicate – organic) and the wide range in concentration of the minor constituents that may be present. The heterogeneous distribution of minor components means that the appropriateness of collection and preparation procedures in providing a representative soil sample must be considered. Many minor components commonly present in soil are essential to biological life processes but become toxic when present in excess. Soil receives minor components from a range of anthropogenic sources and their accumulation is of direct concern for both human and general ecosystem health. The quantification of a small but highly dynamic bioavailable fraction of the total minor component present in soil represents one important topic for analytical chemistry.

Soil is composed of a heterogeneous mixture of solid, gaseous, and aqueous phases, the relative proportions of which can vary both spatially and temporally. The solid matrix consists of an intimate mixture of inorganic (primarily weathering products) and organic (products of biological decomposition) components. The proportion of total soil porosity occupied by water may vary from very low values up to 100% in a fully saturated soil. Soils typically develop a distinctive vertical zonation as a consequence of selective mineral dissolution coupled with

transport and reprecipitation of inorganic components and a decline in organic material.

A precise distinction between what constitutes a ‘major’ or ‘minor’ soil component is difficult to make. For present purposes the term ‘minor component’ is applied to situations where total concentrations are generally <100 µg per g. This may encompass more than 50 minor components many of which could be present at concentrations below 0.1% (Figure 1).

Although most of the minor components are associated with the solid phase a small but functionally significant fraction is present in the soil solution and represents the immediately bioavailable and mobile fraction. The aqueous phase is the primary medium for redistribution and transportation of soluble and particulate bound chemical species within soil. A constant state of flux, resulting in a dynamic equilibrium, exists between solid and solution phases as both respond to local situations of depletion (e.g., plant uptake) or resupply (e.g., application of sewage sludge). Apportioning between solid and solution is sensitive to the prevailing local physicochemical environment through influences of factors such as pH, redox, and electrolyte concentrations.

### Origin of Minor Components

Total amounts of minor components vary widely between soils and are often reflective of a strong geochemical influence (Table 1). Here, soil developed from Serpentine (an ultrabasic, igneous rock) is typically high for Co, Cr, and Ni with the result that even in this ‘natural state’ concentrations are greater than the EC recommended limits for soils receiving metal-containing waste materials (see Table 2). Natural background concentrations have become enhanced

**Figure 1** Comparison of minor components in soils and their abundance in the lithosphere. Open circles mean content in the lithosphere; black circles mean content in topsoils; vertical lines mean values commonly found in top soils. to varying degrees through ‘anthropogenic’ additions. Sources of human derived contamination may reach soil through a combination of ‘passive’ or ‘active’ mechanisms. Examples of the former include atmospheric deposition while the latter may involve the regulated application of ‘contaminated’ materials such as industrial or domestic wastes. The accumulation of Pb in remotely located soils serves to demonstrate that long-distance atmospheric transport occurs. Isotopic Pb signatures allow individual sources of contamination to be identified. Repeated application

of phosphatic fertilizers manufactured from sedimentary deposits containing a Cd impurity provides a further example that has resulted in the widespread contamination of agricultural soils with the potential for direct transfer into the human food chain.

The composition of anthropogenic sources and individual chemical species present is highly variable. Repeated applications of contaminated materials such as sewage sludge have resulted in situations where the long-term accumulation of potentially toxic species represents a potential health risk.

**Table 2** Influence of soil pH on the maximum permissible concentrations (mg per kg per dm) of minor components in soil (CEC, 2000 Commission of the European Communities Working document on sludge: 3rd draft. ENV.E.3/LM.CEC, Brussels)

Elements	Current values proposed values			
	Directive 86/278/EEC	pH 5–6	pH 6–7	pH > 7
Cd	1–3	0.5	1	1.5
Cr	–	30	60	100
Cu	50–140	20	50	100
Hg	1–1.5	0.1	0.5	1
Ni	30–75	15	50	70
Pb	50–300	70	70	100
Zn	150–300	60	150	200

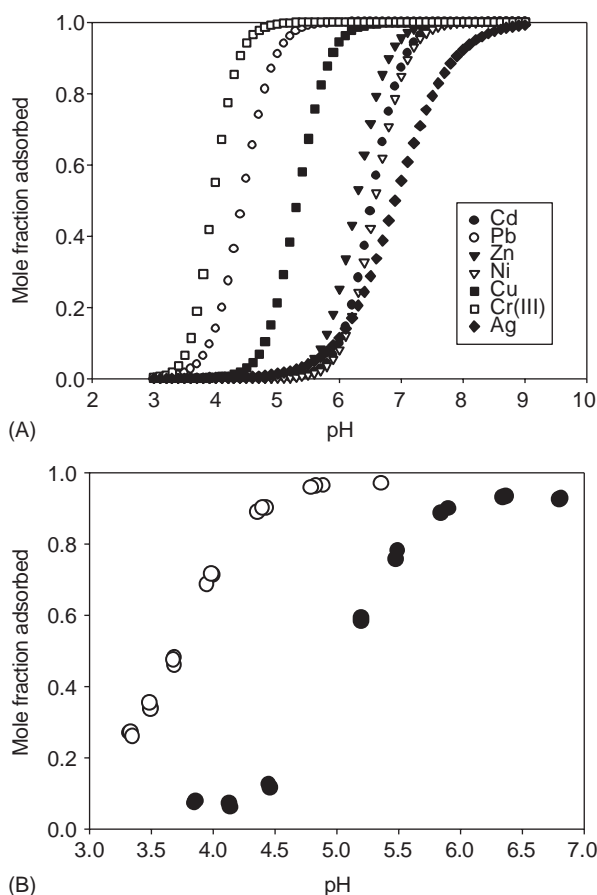

### Wider Significance of Minor Components and Current Regulations

Most minor components while being essential to the biochemical, life processes, also happen to be potentially extremely toxic when present in excess. Defining what constitutes a 'safe' soil concentration is difficult. Guideline concentration limits for soil that is likely to receive contaminated waste are continually under review. Many of these guidelines tend to be based upon a total concentration in spite of the often poor relationship between total and biologically significant fractions. This situation probably reflects the relative ease of determining 'total' concentrations compared to some biologically labile and highly dynamic component. The incorporation of factors that might be influential in determining bioavailability, such as a weighting factor for soil pH, have been attempted (Table 2).

Potential toxicity is sensitive to the prevailing local environment through selective influences on chemical speciation or activity. Toxicity can result from either 'chronic' or more 'acute' type exposures. Overlapping ranges in sensitivities between individual organisms makes the setting of threshold concentrations for individual ecosystems difficult.

### Developments in the Determination of Minor Constituents

A significant early requirement for soil analysis arose from a need to define optimum conditions for crop growth and appropriate dietary intake from feed for animal health purposes and identify soil deficiencies. Recently, research emphasis has changed to consider situations where bioaccumulation and potential toxicity is the primary concern. Bioassays have incorporated a range of test species including plants, earthworms, and, recently, toxicity fingerprinting with a metabolic lux-marked bacterial biosensor.

**Figure 2** (A) Calculated adsorption by a hydrous ferric oxide of several metal cations at a total added metal concentration of  $10^{-6} \text{ mol l}^{-1}$  using the diffuse double layer surface complexation model. (From Dzombak DA and Morel FMM (1990) *Surface Complexation Modeling: Hydrous Ferric Oxide*. New York: Wiley.) (B) Experimentally measured cadmium ( $[\text{Cd}]_{\text{total}} = 0.3 \text{ mmol l}^{-1}$ ) adsorption by O (open circles) and B (filled circles) horizons ( $18.5 \text{ g dm}^{-3}$ ) in  $0.01 \text{ mol l}^{-1} \text{ NaNO}_3$ . (Data from Lumsdon DG (2004) Partitioning of organic carbon, aluminium and cadmium between solid and solution in soils: application of a mineral-humic particle additivity model. *European Journal of Soil Science*, in press.)

Predicting likely bioavailability and the potential for transfer into the human food chain presents a continuing challenge. This requires an understanding of the various factors that interact to influence ion speciation and partitioning between soil and solution phases. Figure 2A demonstrates a modeled response of the influence of pH on adsorption of various species by a hydrous ferric oxide. The important influence that the type (composition) of solid phase has on partitioning is shown in Figure 2B where experimental data for organic (O) and mineral (B) horizons are compared. The two soils behave very differently; at a given pH the proportion of the Cd adsorbed by the organic soil is greater. The need to increase

understanding of the factors affecting solid–solution dynamics is especially apparent for toxicity related studies.

## Distribution of Minor Components in Soil

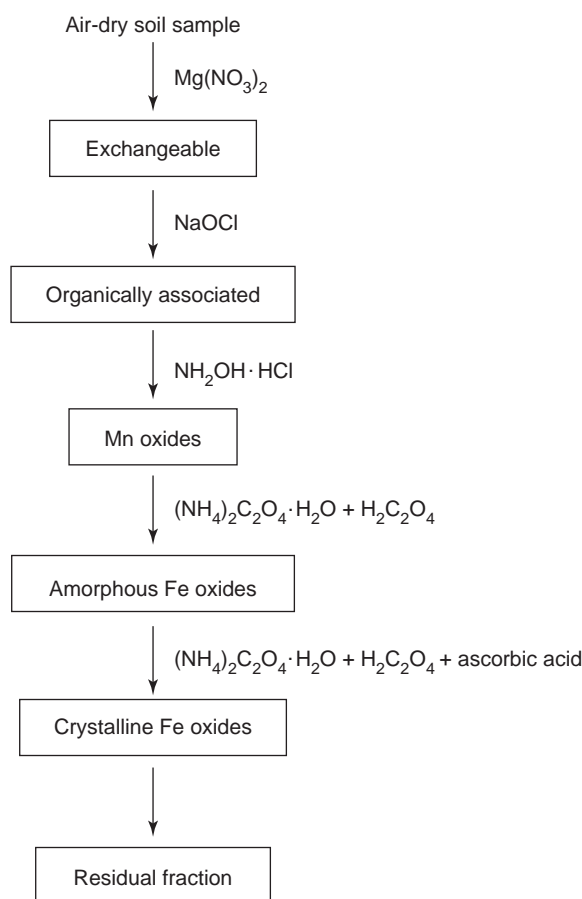

Soil particles differ widely in chemical composition, which introduces a degree of heterogeneity into the spatial distribution of minor components. Chemically reactive species become concentrated within smaller sized particles or associated with secondary surface coatings and must be considered with respect to the collection and preparation of truly ‘representative’ soil samples.

Soil analysis has followed two broad but complementary approaches. The first and probably still most widely performed analysis relies upon measurements made on a solution after an initial solubilization or extraction operation and utilizes readily available techniques and instrumentation. The second involves some form of direct measurement on soil that requires specialist equipment and interpretation. Extraction-based approaches provide intrinsic information capable of describing field-scale spatial and temporal variability. Direct analysis tends to yield detailed compositional information at individual aggregate and subparticle scales. Overlap exists between approaches with both offering multielemental capabilities at the required limits of detection.

### Extraction and Subsequent Analysis

Minor components form a wide range of chemical associations with soil constituents including surface exchange sites, carbonates, metallic oxyhydroxides, and organic matter as well as the ‘residual’ crystalline structures of silicate minerals. This realization underpinned the development of selective procedures including sequential extractions that are designed to preferentially solubilize these individual fractions (Figure 3). Although widely adopted, concern remains as to the chemical rigor of these operationally based procedures. A lack of methodological consistency coupled with issues that arise from soils having different chemical properties makes interlaboratory quality control and standardization difficult. The introduction of internationally agreed standard soil samples is helping to resolve this important issue.

The increased quality of analytical information and greatly improved detection limits has had a positive feedback enabling less aggressive extractants to be employed, which provide an improved quantification of the bioavailable fraction. Parallel developments in the extraction conditions employed have

**Figure 3** Sequential extraction scheme for various soil zinc fractions. (From Perveen Z *et al.* (1994) Redistribution of zinc from sewage-sludge applied to a range of contrasting soils. *Science of the Total Environment* 155: 161–171.)

enabled greater definition of the kinetic parameters regulating depletion and resupply (e.g., diffusive gradients in thin films).

### Direct Analysis

Analysis performed directly on soil has continued to benefit from instrumental improvements, which now readily allow analysis at subparticle scale. Many of the techniques that provide a direct analysis also offer the potential for excellent spatial resolution with possibilities of even some depth resolution whilst also providing information on the chemical associations between individual minor components.

## Soil Sampling and Storage

### Collection

Soil represents a difficult matrix for which to obtain a representative and homogeneous sample. In the field, properties change over relatively short vertical

and also horizontal distances that have been described using intensive sampling and appropriate geostatistical techniques. Variability also occurs within a single well-mixed soil sample and exists across individual soil particle sizes. Separating variability due to natural factors from that arising due to anthropogenic sources will be an increasing requirement.

The collection and subsequent analysis of soil samples can follow one of two broad strategies. Either a number of cores may be taken and analyzed individually, or samples can be combined and thoroughly mixed to provide a single bulked sample. Details of the spatial variation in concentrations are sacrificed in the latter case. Choice of the most appropriate analytical technique requires consideration of detection limits, range of chemical species to be determined, and concentration range to be determined.

### Contamination

It is possible to minimize potential sources of contamination considerably through careful thought and prudent choice of materials likely to contact the soil sample. Soil sieving and milling stages can be particularly prone to introducing contamination; the use of carbon steel, plastic, or aluminum can minimize this.

### Storage

Soil samples stored in an air-dry condition are relatively stable particularly when total contents are to be determined. Samples must be well mixed after long-term storage to minimize the affect of size separation. Storage of soil extracts is much more problematical due to precipitation from solution and sorption processes on the container walls and should be avoided when possible. This is particularly the case for soil solutions or when weak electrolytes are used as extractants. The common method of preserving samples is acidification, but is only suitable when speciation is not required. Biological activity can be minimized by freezing samples or by adding small amounts of toluene.

## Preparation Procedures

There are few situations where pretreatment of the solid sample is not desirable or indeed essential. Invariably the aim is to achieve one or more of the following objectives: (1) sample homogeneity, (2) decomposition, (3) elimination of possible matrix interferences, and (4) preconcentration.

The extent to which any treatment is required varies considerably and depends upon the broad

chemical characteristics of the sample and the analytical method used.

### Sieving and Subsampling

Once collected, soil samples are generally air-dried and passed through a 2 mm sieve. It may be necessary to take into account the weight of discarded material (which is  $> 2$  mm). A more homogeneous sample can be produced using additional milling (e.g., agate ball mill) and is especially recommended for many digestion and direct analysis procedures. Subsampling can be achieved by either coning and quartering or the use of a mechanical riffler.

### Decomposition

**Dissolution** For the majority of soil samples a total dissolution requires the use of an acidic cocktail, which includes hydrofluoric acid and an oxidant to remove the organic component. Less chemically rigorous mixtures include aqua regia ( $\text{HCl}/\text{HNO}_3$  3:1 v/v) and  $\text{HNO}_3/\text{HClO}_4$ , which are often adequate for the nonsilicate bound components. Various digestion and reflux procedures are in common use although care must be taken when either calcareous or organic-rich samples (due to the release of carbon dioxide) are being digested. Flow-through microwave-assisted digestion apparatus permits soil slurries to be continuously processed and analyzed directly. These online approaches offer many potential advantages.

**Fusion** Various fusion melts can be used, but probably the most common uses alkaline borax. Fusion disks can be analyzed directly or after the solidified melt has been dissolved in dilute acid.

**Selective extraction and concentration** Soil digest and extraction solutions often contain excessive concentrations of potentially interfering elements, originating directly from the sample or from the chemicals used during the pretreatment. This can cause instrumental problems, which include for atomic absorption spectrometry (AAS), chemical (ionization suppression), spectral (line overlap), and physical (such as nebulizer blocking caused by high salt levels) interferences. These matrix effects are often more serious in the present context, because of the low analyte concentrations involved. Various separation techniques can help to minimize these effects and include precipitation, preferential complexation, and separation through solvent extraction, or selective chelation onto ion-exchange material. There are also certain selective procedures such as hydride generation for metals such as arsenic and selenium.

Several of these procedures have an additional advantage of introducing a preconcentration step. Complexation and selectivity using chemically active compounds such as ethylenediaminetetraacetic acid or synthetic ion-exchange materials have been used with considerable success for many years. After extraction there are a number of possible analytical options: the resin material may be either analyzed directly by X-ray fluorescence spectrometry or as a solution after digestion or elution of the resin.

**Filtering** It is often important to distinguish between what is present in soil solution as soluble or colloidal/particulate material. An operationally defined filtering stage (0.45  $\mu\text{m}$ ) is commonly employed.

## **Analytical Techniques**

This section is subdivided on the basis of whether the analysis is made directly on the 'solid' soil sample or on a 'solution' after a pretreatment stage. A further division is made on whether the analysis technique determines the total amount present or is capable of distinguishing between chemical species.

### **Direct Analysis of Soil Material**

The majority of techniques capable of direct analysis provides an analysis of the whole sample and has multielement capabilities. Some spatial resolution can be achieved by using, for example, X-ray microprobe attachment in conjunction with electron microscopy.

**Instrumental neutron activation analysis** This is an extremely sensitive technique being especially suited for rare-earth species and requires from 50 to 200 mg of finely ground sample. All trace elements, other than boron, that are essential to plants can be determined. There are few matrix interference effects but specialized irradiation facilities are required making its routine use limited. The high aluminum content of many soil samples produces a highly radioactive matrix but fortunately it has a relatively short half-life (150 s). Digestion of samples after irradiation allows the use of a chemical separation step, resulting in lower detection limits and an extended range of determinable chemical species. One recent analysis of an international standard soil sample reported concentrations of most species were within 10% of the certified values and precision (six replicates) was found within 15%.

**X-ray analysis** Two techniques, X-ray fluorescence (XRF) spectrometry and electron microprobe, are

widely used in soil science. The data produced are complementary. The former technique involves detection by either energy or wavelength dispersive means while the latter is more commonly energy dispersive. XRF can be automated and is capable of providing a rapid and comprehensive preliminary analysis (elements with atomic number  $>11$ ). Samples are commonly presented either as pressed disks of finely milled soil (which may need binding agent) or fused discs (e.g., borate flux). It is possible to produce suitable calibration standards using artificial mixes based upon iron, aluminum, and silicon oxides. Certain of the procedures already discussed can be combined with XRF. An example would be complexation of metals (with ammonium pyrrolidine dithiocarbamate), followed by extraction into chloroform and evaporation on a filter paper.

Use of the microanalysis attachment in conjunction with electron microscopy can provide a visual representation of concentrations. When linked to nondestructive preparation techniques, such as critical point drying, this offers the potential of assessing specific soil processes. Adamo *et al.* used scanning electron microscopy in back-scattered electron mode to examine the soil-root interface of plants grown at a range of soil pH and soil phosphorus concentrations. Excellent spatial resolution is, however, counterbalanced by relatively poor detection limits due to poor spectral resolution resulting in severe peak overlap.

**Spark source mass spectrometry** This technique has considerable potential for soil analysis, but continues to prove to be unpopular. This has been variously attributed to the high cost, major interelement effects, and rather specialized nature of both the equipment and sample preparation procedure. The technique does have particular advantages in that it has a high sensitivity and a wide range of chemical species are detectable.

### **Direct Analysis of Extract Solution**

A wide range of the available atomic spectroscopic techniques are routinely used for soil analysis. Some of the more relevant information for individual instrumental techniques is summarized in **Table 3**.

**Flame and electrothermal techniques** Both atomic absorption and emission have been used, with the former most widely applied to the analysis of minor soil components. Detection limits can often be very similar to the concentration found in extraction solutions of 'natural' soils. While the sampling procedure is easily automated, AAS, it is inefficient (both time and sample volume) for routine multielement

**Table 3** Comparison of some attributes of instrumental techniques commonly employed for soil analysis

	Detection limit (mg per kg or mg l <sup>-1</sup> )	Multielement	Selectivity	Matrix interference	Precision (%)	Accuracy

analysis. It remains useful in cases when only individual elements are required or where complex matrices are involved and can handle total dissolved solids (TDS) up to 10%. Analysis of soil extracts using either flame technique is prone to chemical and physical interferences. Clogging of the burner and nebulizer as a consequence of the high salt contents of many soil extractants is a particular problem. The presence of high concentrations of calcium, magnesium, potassium, sodium, and aluminum in many soil extracts can often cause chemical and background interferences.

Relatively poor detection limits are the main drawback of flame AAS, changing the method of sample introduction by using furnace atomizers can improve detection limits by two orders of magnitude or more. An additional advantage of electrothermal-AAS is the low sample volume requirements of the technique and a reduction of sampling-related interferences (viscosity and burner clogging). It remains an extremely popular technique.

Hydride generation for minor components such as arsenic, selenium, and tin continues to have advantages that include separation of the analyte from the matrix, increased transport efficiency to the point of atomization, and the capability for organometallic speciation.

**Inductively coupled plasmas** The commercial availability of instruments using inductively coupled plasmas (ICP) means they are now in routine use. High initial and running costs are offset against the multi-element capability of the techniques, some being capable of determining 30 elements simultaneously. ICP offers numerous advantages with respect to analysis of soil extracts when compared to conventional flame techniques. A wide linear range, often covering more than three orders of magnitude, is especially suited to analysis of soil. It is suitable for all elements other than halides, inert gases, and

atmospheric gases. Many of the interferences commonly associated with flame techniques are less significant. Some spectral (overlap of emission lines) and matrix interferences (affecting excitation conditions within the plasma and nebulization efficiency) do occur. Various 'online' cleanup or concentration procedures have been reported, such as hydride generation for the simultaneous determination of arsenic, antimony, bismuth, selenium, and tellurium.

The increasing availability and superior performance of mass spectrometric (MS) detection systems means these are replacing optical (emission) based systems for routine use. Each has its own particular attributes; the MS system does allow higher sensitivities to be achieved and can provide additional isotopic information that may be particularly useful where pollution sources have a unique isotope fingerprint. The main disadvantage of MS for soil extracts is related to matrix interferences particularly regarding the use of organic solvents. Improved nebulizer design means it is possible to analyze soil slurries (up to 10% TDS) directly.

## Speciation

The increasing emphasis for information on speciation and bioavailability assessments has been discussed earlier; the following techniques allow direct speciation on soil extraction solutions.

### Electrochemical Methods

Anodic stripping voltammetry, potentiometric stripping voltammetry, and differential pulse polarography are used for the simultaneous determination of up to 10 analytes at extremely low concentrations (detection limits <0.01 µg l<sup>-1</sup>). Electroanalytical techniques are applicable for ~30 elements. Stripping analysis allows differentiation between chemical forms but is subject to interference from adsorption

and poisoning by organic compounds onto the mercury electrode. Additional interferences include peak overlapping due to similarity of redox potentials and the formation of intermetallic compounds between the deposited metals.

### Spectrophotometric Procedures

A wide range of spectrophotometric and fluorometric methods have been developed that are extremely sensitive and are easily adaptable for automated analysis. The usefulness of these methods can be reduced because of a nonspecific nature and interferences caused by soluble organic material.

### Liquid Chromatography

Numerous specialized liquid chromatography (LC) systems and ion-exchange chromatography in particular have been used to determine a wide selection of minor components that include selenium, arsenic, molybdenum, chromium, and boron. Various detection systems have been employed, including AAS, ICP-atomic emission spectroscopy, electrochemical, and conductivity. A concentrator column can also be included inline.

### Isotopic Analysis

Isotopic investigations are widely used in soil/plant nutritional and pollution studies. Introduction of an isotope by design or accident enables specific fractions or pools to be labeled, making it possible to follow rates of exchange between soil matrices: soil solution–plant uptake and drainage water. The usefulness of this technique ultimately depends upon the availability of an isotope, with a suitable half-life. A number of recent pollution incidents have involved both stable (lead petroleum additions) and radioisotopes (including  $^{137}\text{Cs}$  and  $^{125}\text{I}$ ).

## Examples of Applications for Analysis of Soil Minor Components

### Monitoring of Contaminated Sites

Onsite total analysis by energy dispersive XRF spectrometry is increasingly popular. When linked with various contour-mapping software packages, the technique can give a rapid assessment of a suspected pollution incident.

### Estimation of Soil Erosion Rates and Geographical Sourcing of Material

A recent example using the artificial radionuclide  $^{137}\text{Cs}$  was used to estimate the net ( $\sim 35$  year) soil

flux (erosion and deposition) in a  $5 \times 5 \text{ km}^2$  area of East Anglia (UK). The continuous spatial variation of  $^{137}\text{Cs}$  over this area was assessed and the redistribution of soil by wind investigated. Similar approaches have been used to successfully quantify soil erosion by water.

### Analysis of Road Dusts and Roadside Soils

Elevated concentrations of platinum group species (Pt, Pd, and Rh) have been detected in roadside media by ICP-MS after microwave digestion and cation exchange. The various ratios in road dusts and soils are consistent with known automobile catalytic converter compositions although no direct relationship between abundance and traffic volume was evident. The significance of other local factors such as driving style, topography, road drainage, and climate were suggested.

### Introduction

Soil organic matter (SOM) is commonly defined as the organic fraction of the soil exclusive of undecayed plant and animal residues. Sometimes, in a broader definition, SOM encompasses the totality of organic material (living and nonliving) present in soils, including thus, living microorganisms and undecayed residues. In cultivated soil, synthetic or natural organic compounds may also be introduced in the soil (sewages, pesticides, etc.). The terms SOM and humus have often been used synonymously.

SOM plays a primordial role in the productivity of soils, being a major reservoir and source of N, P, S, and other nutrients indispensable for the plant growing, and an energy source for heterotrophic soil fauna. Also, SOM has environmental importance on issues related with erosion, pollution, and global climate change.

By convention, soil samples used in the analysis have to be air-dried, crushed, and sieved to 2 mm. By convention, chemical, physical, and mineralogical analysis are made on the <2 mm material. Therefore, SOM includes only those organic materials that accompany soil particles through a 2 mm sieve.

SOM is either analysis in terms of quantity, or of quality depending on the final objectives.

### Quantitative Analyses

SOM content is highly variable in soils (variations with depth and soil type). Major elements are C, H, O, N, P, and S. Organic carbon (C) is the major component of SOM. It is difficult to quantitatively

estimate the amount of OM present in a soil. Procedures used in the past involved determination of the change in weight of a soil sample resulting from destruction of organic compounds by H<sub>2</sub>O<sub>2</sub> treatment or by ignition at high temperature. Both techniques are subject to error. The H<sub>2</sub>O<sub>2</sub> method does not quantitatively remove organic matter, and the ignition method gives an overestimate because both inorganic and organic constituents lose weight during heating. Alternatively, SOM quantity is assessed through organic C content: SOM = organic C × 1.724. This last coefficient, called the van Bemmelen factor, is used by assuming that SOM contains 58% organic C. It is clear that it is only an approximation, as the proportion of organic C in SOM is highly variable. Published organic C–organic matter conversion factors for surface soils have varied from 1.5 to 2.5. The appropriate factor must be experimentally determined for each soil. Although neither the direct determination of organic matter nor the calculation of organic matter content is completely accurate, the best procedures currently available are described here. Because of the problem associated with determining the organic matter content of a soil, it is strongly suggested that investigators determine and report the organic C concentration as a measure of the organic matter in a soil.

### Total Carbon in Soil

Total C in soils is the sum of both organic and inorganic C. Most organic C is present in the soil organic matter fraction, whereas inorganic C is largely found in carbonate minerals. Not all soils contain inorganic C because of dissolution during soil formation of carbonate minerals originally present in parent material. However, organic C is present in all agricultural soils. In soils formed from calcareous parent material under arid conditions, it is not unusual for the inorganic C concentration to exceed the amount of organic C present. Organic C is mainly in the soil organic fraction, which consists of the cells of microorganisms, plant, and animal

### Introduction

Soil organic matter (SOM) is commonly defined as the organic fraction of the soil exclusive of undecayed plant and animal residues. Sometimes, in a broader definition, SOM encompasses the totality of organic material (living and nonliving) present in soils, including thus, living microorganisms and undecayed residues. In cultivated soil, synthetic or natural organic compounds may also be introduced in the soil (sewages, pesticides, etc.). The terms SOM and humus have often been used synonymously.

SOM plays a primordial role in the productivity of soils, being a major reservoir and source of N, P, S, and other nutrients indispensable for the plant growing, and an energy source for heterotrophic soil fauna. Also, SOM has environmental importance on issues related with erosion, pollution, and global climate change.

By convention, soil samples used in the analysis have to be air-dried, crushed, and sieved to 2 mm. By convention, chemical, physical, and mineralogical analysis are made on the <2 mm material. Therefore, SOM includes only those organic materials that accompany soil particles through a 2 mm sieve.

SOM is either analysis in terms of quantity, or of quality depending on the final objectives.

### Quantitative Analyses

SOM content is highly variable in soils (variations with depth and soil type). Major elements are C, H, O, N, P, and S. Organic carbon (C) is the major component of SOM. It is difficult to quantitatively

estimate the amount of OM present in a soil. Procedures used in the past involved determination of the change in weight of a soil sample resulting from destruction of organic compounds by H<sub>2</sub>O<sub>2</sub> treatment or by ignition at high temperature. Both techniques are subject to error. The H<sub>2</sub>O<sub>2</sub> method does not quantitatively remove organic matter, and the ignition method gives an overestimate because both inorganic and organic constituents lose weight during heating. Alternatively, SOM quantity is assessed through organic C content: SOM = organic C × 1.724. This last coefficient, called the van Bemmelen factor, is used by assuming that SOM contains 58% organic C. It is clear that it is only an approximation, as the proportion of organic C in SOM is highly variable. Published organic C–organic matter conversion factors for surface soils have varied from 1.5 to 2.5. The appropriate factor must be experimentally determined for each soil. Although neither the direct determination of organic matter nor the calculation of organic matter content is completely accurate, the best procedures currently available are described here. Because of the problem associated with determining the organic matter content of a soil, it is strongly suggested that investigators determine and report the organic C concentration as a measure of the organic matter in a soil.

### Total Carbon in Soil

Total C in soils is the sum of both organic and inorganic C. Most organic C is present in the soil organic matter fraction, whereas inorganic C is largely found in carbonate minerals. Not all soils contain inorganic C because of dissolution during soil formation of carbonate minerals originally present in parent material. However, organic C is present in all agricultural soils. In soils formed from calcareous parent material under arid conditions, it is not unusual for the inorganic C concentration to exceed the amount of organic C present. Organic C is mainly in the soil organic fraction, which consists of the cells of microorganisms, plant, and animal

residues at various stages of decomposition, stable 'humus' synthesized from residues, and highly carbonized compounds such as charcoal, graphite, and coal (elemental forms of C). Organic C in soil may be estimated as the difference between total C and inorganic C. Organic C can be determined directly by total C procedures after removal of inorganic C or by rapid dichromate oxidation–titration techniques. Procedures involving a total C analysis generally recover all forms of organic C in soils, whereas dichromate oxidation procedures recover variable proportions of elemental C (e.g., charcoal) and, in some procedures, variable amounts of organic C contained in 'humus'. Calcite and dolomite are the principal carbonate minerals present in soil, and most inorganic C is associated with these compounds. However, in some alkaline soils, significant amounts of inorganic C may be present as soluble carbonate –  $\text{CO}_3^{2-}$  and bicarbonate –  $\text{HCO}_3^-$  salts.

Total C determinations for soil involve conversion of all forms of C in soils to  $\text{CO}_2$ , by wet or dry combustion and subsequent quantification of evolved  $\text{CO}_2$ , by gravimetric, titrimetric, volumetric, spectrophotometric, or gas chromatographic techniques. Dry combustion is carried out by heating a soil–catalyst mixture in a resistance furnace or induction furnace in a stream of  $\text{O}_2$ , or  $\text{CO}_2$ -free air, followed by quantification of the evolved  $\text{CO}_2$ . Wet combustion is normally carried out by boiling a soil sample with a mixture of  $\text{K}_2\text{Cr}_2\text{O}_7$ ,  $\text{H}_2\text{SO}_4$ , and  $\text{H}_3\text{PO}_4$  in a closed system flushed with a stream of  $\text{CO}_2$ -free air and absorption of the evolved  $\text{CO}_2$ , in a tarred weighing bulb filled with Ascarite. Alternatively, wet combustion may be carried out in a van Slyke–Neil apparatus and evolved  $\text{CO}_2$ , estimated by manometric procedures.

Analytical procedures used for determining total C in soils must quantify both inorganic and organic forms. In humid regions where extensive leaching of the soil profile has occurred, organic C will be the predominant form present. In arid and semiarid regions, carbonate minerals (e.g., calcite, dolomite) along with soluble carbonate salts will constitute a significant percentage of the total C. Two basic approaches are used to quantify total C in soils, namely, dry combustion and wet combustion. In both instances, the  $\text{CO}_2$  liberated from organic and inorganic C is determined through volumetric, titrimetric, gravimetric, and conductimetric techniques. An apparatus for performing total C analysis by dry combustion can be fabricated from conventional laboratory glassware and a medium-temperature ( $\sim 1000^\circ\text{C}$ ) resistance furnace. Dry combustion procedures using either high-temperature ( $\sim 1500^\circ\text{C}$ ) or induction furnaces are most commonly found in

commercially available, automated total C analyzers. The majority of dry combustion methods employ gravimetric determination of  $\text{CO}_2$ . Wet combustion methods for total C employ a strong oxidant ( $\text{K}_2\text{Cr}_2\text{O}_7$ ) in an acidic digestion mixture for quantitative oxidation of organic C and dissolution of carbonate minerals.

### **Wet Oxidation**

Undoubtedly, the most widely used method worldwide, for historical and cost reasons, to determine organic C content is a wet oxidation of organic C in the presence of dichromate ( $\text{Cr}_2\text{O}_7^{2-}$ ) in highly acidic medium, and back-titration with ferrous sulfate of excess dichromate:

This method was proposed by Shollenberger in 1927 and then by Walkley and Black in 1934, who gave their names to this method. The oxidation occurs at a temperature of *c.*  $120^\circ\text{C}$  and unfortunately the recovery is incomplete, an average factor of 76% proposed by Walkley and Black is used. Other studies have showed that the recovery may vary between 60 and 86%. Therefore, it must be highlighted that this method gives only an approximate or semiquantitative estimate of C. Several authors have proposed modifications, mainly heating the reaction and most laboratories nowadays use  $150^\circ\text{C}$ .

In any case, all these modifications give low recovery (2–36%) of carbonized material (e.g., charcoal, soot) that may exist in soil due following combustion of the aboveground biomass.

### **Dry Combustion**

In combustion, all forms of C are converted to  $\text{CO}_2$  followed by a quantification of the evolved  $\text{CO}_2$ . In soils containing inorganic C, generally in the form of carbonates, an acidic pretreatment must be effected. Soil sample must be prepared in a fine powder ( $< 80$ – $100$  mesh). The sample is heated in an oven at  $1000$ – $1500^\circ\text{C}$  for quantitative recovery of C. Modern instruments perform simultaneous determination of C, N, and H and sometimes O and S. Analyses used microsamples of about 50–100 mg.

### **Spectroscopic Techniques**

Improving estimates of C in soil is currently hindered by lack of rapid, accurate, and precise analysis method. Two novel approaches based on spectroscopy are being developed and proposed even for *in situ* soil analysis.

Near-infrared reflectance spectroscopy (NIRS) is an analytical technique that correlates diffusely

reflected near-infrared radiation with the chemical and physical properties of materials. Near-infrared spectra (wavelengths in the 400–2498 nm range) are dominated by weak overtones and combinations of fundamental vibrational bands for H–C, H–N, and H–O bonds from the mid-infrared region. Soil minerals, organic matter, and moisture are the major components of soils, with distinct spectral features in the visible and near-infrared regions.

Analytical applications of NIRS have been explored since the early 1950s. However, owing to instrumental difficulties, its use as a quantitative approach started only 30 years later, together with the development and the widespread use of computers. As the coupling between equipment and microcomputers became easier and faster, obtaining and storing large amounts of data became possible.

The NIRS technique is rapid, effective, convenient, accurate, nondestructive, does not consume the sample, and does not present danger to the operator. Moreover, it provides a reduction in both reagent consumption, and the time needed for performing the analysis, in addition to permitting *in situ* analysis. These advantages confer particular characteristics on the technique, making it useful for routine soil analysis and online control in industrial processes.

In the NIRS technique, the spectra need to be processed by using either principal component regression (PCR), multiple linear regression (MLR), stepwise multiple linear regression (SMLR), maximum  $r^2$  improvement (MAXR) model, Fourier transform filter, multiplicative scattering correction (MSC), and partial least-squares regression (PLSR).

PLSR nowadays is a reference method for multivariate calibration and its utilization has overcome limitations in the use of multiple linear regressions. In the PLSR approach, the full spectrum is used to establish a linear regression model, where the significant information contained in the near-infrared spectra is concentrated in a few latent variables that are optimized to produce the best correlation with the desired property to be determined.

The second approach named laser-induced breakdown spectrometry (LIBS) is based on atomic emission spectroscopy. In this method, a laser is focused on a solid sample and forms a microplasma that emits light characteristics of the elemental composition of the sample. The emitted light is collected, spectrally resolved, and detected to monitor concentrations of elements via their unique spectral signatures. When calibrated, the method can also provide quantitative measurements.

The main advantage of LIBS is that it simplifies the conventional methodology by avoiding laborious chemical steps, e.g., the preparation and dissolution

of the soil sample. Further, this technique allows the direct chemical analysis of the solid sample by its vaporization achieved by interaction with a laser beam of adequate frequency and intensity. Because of the lack of pretreatment of the material, as well as the speed of analysis, not mentioning the possibility of *in situ* analysis, this technique offers an attractive solution for a wide range of applications.

This promising new method, however, has potential drawbacks, namely interference from Fe at approximately 248 nm. Additional testing of LIBS is required to understand the effects of soil properties such as texture, moisture content, and mineralogical composition (e.g., silicon content) on LIBS measurements.

## Qualitative Analyses

### Historical Review

The first attempt to isolate organic substance from soil appears to have been made by F.K. Achard in 1786, and T. de Saussure is usually credited for introducing the term ‘humus’ (Latin equivalent of soil) to describe the dark-colored organic material in soil. Several researchers tried to find out the chemical nature of humus. By the end of the nineteenth century, it had been firmly established that humus was a complex mixture of organic substances that were mostly colloidal in nature and which had weakly acidic properties.

During the first half of the twentieth century renewed efforts were deployed to classify organic substances and to determine their chemical nature and structure. Most of the approaches proposed classification based on solubility characteristics: humic acid (soluble in alkali, insoluble in acid), fulvic acid (soluble in alkali and acid), hyalomelanin acid (alcohol-soluble part of humic acid), humin (insoluble in alkali).

The modern-day concept recognizes that soil organic matter includes a broad spectrum of organic constituents with two major types: on one hand, compounds belonging to well-known classes of organic chemistry such as amino acids, carbohydrates, and lipids, and on the other hand, a series of high-molecular-weight compounds formed by secondary synthesis.

The International Humic Substance Society was founded in 1981 to bring together scientists in the coal, soil, and water sciences with interests in humic substances. Recommended methods are available at [www.ihss.gatech.edu](http://www.ihss.gatech.edu).

More recently, soil scientists proposed the separation of SOM in physical fractions according to different sizes and/or densities. These methods intend to

fractionate SOM into pools of different turnover times and bioavailability as they split SOM into free particulate OM and OM associated with soils minerals. Most physical fractionation procedures include different types of ultrasonic treatments for dispersion. Although there is no single fractionation procedure applicable for all soil types, the fraction sizes separated are commonly 200, 50, 2, and 0.2  $\mu\text{m}$ . However, a major concern remains the lack of standardization of ultrasonic energies and time of application.

The advantage of this approach resides in its concept that modeled SOM into compartments. This concept has been and is still actively being used to develop and calibrate mechanistic models of SOM dynamics.

The methods that have been used for obtaining information on the chemical structure can be divided into two groups, degradative and nondegradative methods.

### **Degradative Methods**

Degradative methods include oxidative and reductive degradation, hydrolysis, various types of irradiation, thermal analysis, and biological degradation. Of these, the oxidative method is the most informative. Several reagents have been used for the oxidation of humic substances, such as potassium permanganate, copper(II) oxide, aqueous chloride (under alkaline conditions); nitric acid, peracetic acid, hydrogen peroxide, ultraviolet radiation (under acidic conditions). Premethylation is important for obtaining good yields. Alkaline permanganate oxidation seems to be the best method, from the standpoints of producing relatively large amounts of identifiable digestion products and providing significant information on the chemical structures of humic substances. All oxidative degradations of soil substances essentially produce aliphatic substances (alkanes, fatty acids, and aliphatic carboxylic acids), phenolic acids, and benzenecarboxylic acids. Soil humic acids and soil fulvic acids yield similar quantities of aliphatic compounds on oxidation, whereas the oxidation of soil fulvic acids yields more phenolic acids but less benzenecarboxylic acids in comparison to soil humic acids. Results obtained from degradative techniques must be treated with care in order to avoid overinterpretation. Several of the compounds identified in many digests could be artifacts of the reaction processes and conditions.

### **Nondegradative Methods**

Among the nondegradative methods employed are infrared and UV-visible spectroscopy, spectrofluorimetry, electron spin resonance spectroscopy, and

nuclear magnetic resonance (NMR) spectroscopy. Very little information is obtained from any of the other spectroscopic methods. The study of humic substances is the study of complicated, ill-defined mixtures. Most of the physical and chemical methods of investigation are confined to simple systems and depend on the analyst's skill and ability to interpret the data. In applying any spectroscopic method to humic substances, measurement is taken of the summation of the signals of the numerous components in the mixture which respond to that particular frequency range, with all signals superimposed upon each other. What is measured is the net or average response of these particular components in the assemblage. In the case of humic substances, deciphering this garbled message into chemically meaningful information is, at best, a formidable task.

### **Infrared Spectroscopy**

With a few exceptions, all infrared spectra of humic substances have been measured in dry solid samples, and the pressed-pellet method has been used almost exclusively. The spectrum of humic acid consists of relatively few bands that are very broad. The broadness of the bands reveals that humic substances are complex mixtures where a particular type of functional group can exist in a wide variety of chemical environments, each characterized by slightly different force constants for its bonds. Fourier-transform infrared (FTIR) spectroscopy allows the samples to be observed in their native wet state and avoids the shifts in chemical equilibrium which must necessarily accompany the drying process.

### **Raman Spectroscopy**

Attempts to measure the Raman spectra of humic substances have been unsuccessful to date: the relatively intense fluorescence exhibited by the humic substances obscures any Raman signal that may be present.

### **Ultraviolet-Visible Spectroscopy**

The UV-visible spectra of humic substances are generally featureless and the technique has little value for studying functionality of humic substances and cannot be used for the direct determination of functional groups in these materials. Nevertheless, UV-visible spectroscopy does have other useful applications such as the estimation of the degree of humification using  $E_4/E_6$  ratios (the ratio of the absorbance at 465 nm to that at 665 nm) and for determining the concentration of dissolved humic substances based on Beer's law plots.

### Spectrofluorimetry

Humic substance groups emit in a spectral region relatively free from interferences by other groups. Measurement of the fluorescence is a relatively selective method of analysis. Fluorescence cannot be used for the direct determination of functionality.

### Electron Spin Resonance Spectroscopy

The electron spin resonance (ESR) spectrum of humic and fulvic acids consists of a single line identified by its position and width. In general, the ESR spectra are devoid of hyperfine splitting. The ESR spectra of humic substances contain relatively little data and they result from only a small fraction of the total number of molecules that comprise the humic and fulvic acid. However, ESR yields some information on the nature of free radicals in humic substances. Comparison of the ESR properties among humic fractions reveals that fulvic acids contain greater quantities of free radicals than humic acids.

### Nuclear Magnetic Resonance Spectroscopy

This is the most promising nondegradative technique for humic structural analysis. This is primarily due to two fundamental instrumental advances: the Fourier transform technique and the cross-polarization/magic-angle spinning (CP/MAS) technique which allows the acquisition of  $^{13}\text{C}$  NMR spectra from solid samples. The  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra of all humic substances are highly resolved and exhibit several peaks.

Although SOM has been studied extensively by spectroscopic methods, only recently have investigators turned to NMR techniques to understand its structure. This is due largely to the fact that in the late 1960s and early 1970s problems associated with the low sensitivity of  $^{13}\text{C}$  NMR spectroscopy were overcome. The technique of pulse Fourier transform spectroscopy uses multichannel excitation to allow many scans to be recorded and averaged in a comparatively short time. Much higher signal-to-noise ratios may be obtained than with conventional methods and this has allowed otherwise unobtainable spectra of complex mixtures to be recorded.

NMR is now useful in measuring a range of structural groups in soils and soil extracts, both in solution and the solid state. Studies are not solely confined to the  $^{13}\text{C}$  nucleus.  $^1\text{H}$ ,  $^{29}\text{Si}$ ,  $^{27}\text{Al}$ ,  $^{15}\text{N}$ , and  $^{31}\text{P}$  can also be studied in soils and information on functional group content can be obtained readily. However, operation of a new-generation NMR spectrometer requires a high degree of skill and training. The soil chemist does not normally have this background and will require the NMR specialist to produce a spectrum.

Theoretically, it should be possible to study any element present in a soil by NMR. However, there are a number of limitations. Some nuclei are intrinsically insensitive and if present in only trace concentrations, cannot be detected. This is particularly troublesome for elements for which rare nuclides have to be studied. A further problem is that the width of the lines in the NMR spectra can be greater than the differences between individual resonance frequencies so that whatever the structure, only one broad line is obtained. As already noted, to date only a few nuclei ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{27}\text{Al}$ ,  $^{29}\text{Si}$ ,  $^{15}\text{N}$ ,  $^{31}\text{P}$ ) have been studied successfully in soils, but others are almost certain to be exploited in the future.

### Isotopic Ratio

The isotopic ratio provides information on the origin of humic substances. During biochemical and chemical reactions, the isotopes of a given element undergo fractionation, which depends not only on their mass, but also on the nature of the reaction. Isotopic ratios, in particular  $^{13}\text{C}/^{12}\text{C}$ , depend on the organic matter evolution and enable the origin of the organic matter to be specified to some degree. The humic substances (primarily as fulvic acids) in deep ocean waters have been established to be 3000–6000 years BP with a  $\delta^{13}\text{C}$  of  $-22$  to  $-23\text{‰}$ . All stream humic substances analyzed to date have  $^{14}\text{C}$  ages near zero (all modern carbon) with  $\delta^{13}\text{C}$  values within  $-25$  and  $-28\text{‰}$ . The  $^{14}\text{C}$  and  $\delta^{13}\text{C}$  values for soil humic substances vary considerably. The  $^{14}\text{C}$  age of humic acids in soils varies from a few hundred to several thousand years;  $\delta^{13}\text{C}$  values range from  $-25$  to  $-31\text{‰}$ . Such range for soils may reflect cropping practices and residue management, the methods used for isolation of fulvic and humic acids and sampling techniques rather than true pedogenic differences.

### Structural Models

Structural representations of humic and fulvic acids are purely hypothetical and should just be considered as an attempt to rationalize chemical behavior. Several structural models have been proposed based on data gathered from degradative and nondegradative models. The different proposed models should be considered as complementary since each emphasizes certain particular properties. Briefly, humic acids are macromolecular and complex, and composed of substituted aromatic and aliphatic hydrocarbon core materials. It is probable that some aliphatic and aromatic ring compounds are heterocyclic with N, O, or S as the heteroatom. Segments or some side-chain components in the structures are substantially hydrophobic. In general, however, the

primary structures contain significant amounts of polar substituents, incorporating oxygen in a variety of functional groups. Peptide and saccharide materials can be linked covalently to the core. The following observations can be made:

1. Fulvic acids are generally characterized by their lower levels of total and aromatic carbon.
2. The oxygenated sites, especially carboxylates, are more numerous in fulvic than in humic acids. Studies using NMR seem to indicate that this excess of carboxylates is mostly aliphatic in nature.
3. The free radical content is appreciably lower for fulvic acids than for humic acids.
4. The degree of aromaticity of soil humic and fulvic acids has been estimated to be 70% on the basis of the analysis of the products of their oxidative degradation. There is little information on the degree of aromaticity of water fulvic acids, the autochthonous fraction being more aliphatic.

## Introduction

Glass is a product of cooling a melt that becomes solid without crystallization. This process results in the formation of a continuous polymeric network that includes structural units of the network-forming component(s) (network formers). This network is irregular and unsymmetrical. Among network formers, the so-called glass formers are marked out. These compounds are able to form glasses without other components being added. Other important constituents of glasses are the so-called modifiers. These

substances do not build into the glass network. They either facilitate the transition of the main component to the glassy state (vitreous state) or modify significantly the properties of glasses.

Glasses are an instance of amorphous solids. Most glasses are transparent or translucent.

## Typical Constituents of Glasses

Glasses can be divided into various types according to their chemical composition. Both inorganic and organic substances can be used to produce glasses.

Organic glasses are polymers with an irregular sequence of monomers (as in polystyrene) or polymers with such complex molecules that they cannot form a compact regular network under cooling. Organic glasses are also known as optical polymers.

Inorganic glasses can be divided into two main groups. Simple glasses such as metallic, halide,

primary structures contain significant amounts of polar substituents, incorporating oxygen in a variety of functional groups. Peptide and saccharide materials can be linked covalently to the core. The following observations can be made:

1. Fulvic acids are generally characterized by their lower levels of total and aromatic carbon.
2. The oxygenated sites, especially carboxylates, are more numerous in fulvic than in humic acids. Studies using NMR seem to indicate that this excess of carboxylates is mostly aliphatic in nature.
3. The free radical content is appreciably lower for fulvic acids than for humic acids.
4. The degree of aromaticity of soil humic and fulvic acids has been estimated to be 70% on the basis of the analysis of the products of their oxidative degradation. There is little information on the degree of aromaticity of water fulvic acids, the autochthonous fraction being more aliphatic.

## Introduction

Glass is a product of cooling a melt that becomes solid without crystallization. This process results in the formation of a continuous polymeric network that includes structural units of the network-forming component(s) (network formers). This network is irregular and unsymmetrical. Among network formers, the so-called glass formers are marked out. These compounds are able to form glasses without other components being added. Other important constituents of glasses are the so-called modifiers. These

substances do not build into the glass network. They either facilitate the transition of the main component to the glassy state (vitreous state) or modify significantly the properties of glasses.

Glasses are an instance of amorphous solids. Most glasses are transparent or translucent.

## Typical Constituents of Glasses

Glasses can be divided into various types according to their chemical composition. Both inorganic and organic substances can be used to produce glasses.

Organic glasses are polymers with an irregular sequence of monomers (as in polystyrene) or polymers with such complex molecules that they cannot form a compact regular network under cooling. Organic glasses are also known as optical polymers.

Inorganic glasses can be divided into two main groups. Simple glasses such as metallic, halide,

chalcogenide, and oxide glasses are formed by components of the same chemical origin. Most common silicate glasses are examples of oxide glasses. Complex glasses such as oxychalcogenide or metal-oxide glasses are formed by components belonging to different types of chemical compounds.

As, B, C, Ge, P, S, Se, Si, and Te can form elemental glasses. Among such glasses, the most important are noncrystalline silicon glass, used as the working substance of solar batteries, vitreous carbon glass, used to produce crucibles and protective layers, and selenium glass, used as a photosensitive material in copying techniques.

Metallic glasses can be produced under very rapid quenching of the melt; the quenching rate can be up to  $100\text{ K s}^{-1}$ . Metallic glasses are also known as amorphous metals. Al, Cu, Pb, and Sn form metallic glasses most easily. To make glasses on a base of Ni, Fe, Co, Mn, or Cr, it is necessary to add modifiers such as B, C, P, S, Si, or others. The structure of metallic glasses is characterized by a dense random packing of atoms. Amorphous metals are used in practice mostly as high-quality soft-magnetic materials.

Fluorides of some metals are practically important for halide glasses. Fluoroaluminate and fluorozirconate glasses are examples of oxyhalide glasses. They are transparent in the infrared (IR) range and are candidate materials for producing optical waveguides with an extremely low level of light losses.

Chalcogenide glasses are formed by sulfides, selenides, and tellurides of some elements, for example  $\text{B}_2\text{S}_3$ ,  $\text{SiS}_2$ ,  $\text{Sb}_2\text{S}_3$ ,  $\text{P}_4\text{Se}_4$ ,  $\text{B}_2\text{Se}_3$ , and  $\text{As}_2\text{Te}_3$ . They are used as IR-transparent media, semiconductors, and materials for ion-selective electrodes.

Oxide glasses are formed from the oxides of the type  $\text{R}_2\text{O}_3$  ( $\text{B}_2\text{O}_3$ ,  $\text{As}_2\text{O}_3$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{Sb}_2\text{O}_3$ ),  $\text{RO}_2$  ( $\text{SiO}_2$ ,  $\text{GeO}_2$ ,  $\text{TiO}_2$ ), and  $\text{R}_2\text{O}_5$  ( $\text{P}_2\text{O}_5$ ). Of special importance is silica glass.  $\text{SiO}_2$  forms structural units of  $\text{SiO}_4$  in which the silicon atom is placed in the center of a tetrahedron and oxygen atoms occupy the vertices. One oxygen bond is directed to the central atom, and the second may be directed to another tetrahedron with a central silicon atom. Silica glass has some unique properties. It cannot be deformed up to  $1000^\circ\text{C}$ , it is thermal shock resistant, it displays high bulk and surface electrical resistivity, and it is ultraviolet (UV)-visible transparent, though it has a high melting and can hardly be transformed into glassware. The high cost of silica glass limits its application to special glassware such as in optical components operating at high temperatures, in fiber-optics communication, and in chemical glassware.

Silica is the major component of silicate glasses, which constitute more than 98% of commercial glasses. Silicate glasses include silica together with

other network-forming oxides. They are used widely in building, transport, instrument making, decorative art, etc.

Silicate glasses contain modifiers such as Na, K, Li, Ca, Mg, Ba, and Zn ions that affect the properties of glasses. In addition to the constituents added to glasses to influence their properties, other constituents are added for melting and refining ( $\text{F}^-$ ,  $\text{As}_2\text{O}_3$ ,  $\text{Sb}_2\text{O}_3$ ,  $\text{SO}_3$ ) or for coloring ( $\text{Cr}_2\text{O}_3$ ) or decolorizing ( $\text{CoO}$ ,  $\text{NiO}$ , Se). Glasses always include constituents that are transferred as a result of corrosion of the refractory materials of the pots or ovens in which the glass is melted ( $\text{Al}_2\text{O}_3$ ,  $\text{ZrO}_2$ ) or are presented as impurities in the raw materials used to make the glass ( $\text{Fe}_2\text{O}_3$ ).

The oldest and most common are soda-lime-silica glasses, which contain 12–16% alkali (mainly  $\text{Na}_2\text{O}$ ), 10–12% alkaline-earth oxides ( $\text{CaO}$ ,  $\text{MgO}$ ), and  $\sim 71\%$   $\text{SiO}_2$ . This type includes window glasses, container glasses, glass bricks, and certain types of glass fibers.

Borosilicate glasses are characterized by the presence of a greater amount ( $>80\%$ ) of  $\text{SiO}_2$  (ISO 33853). These glasses have good hydrolytic and thermal shock resistance and are used for large-scale technical applications in the chemical, pharmaceutical, and food industries and for laboratory apparatus. Alkali lead silicate glasses usually contain  $\text{PbO}$  ( $>10\%$ ),  $\text{SiO}_2$  (54–58%) and alkali (14%, mainly  $\text{K}_2\text{O}$ ). Glasses of similar composition are used for making lead crystal as, for instance, in jewelry and expensive drinking glasses (ISO 7086). Lead alkali silica glasses with  $>30\%$   $\text{PbO}$  have good electrical resistance properties and are therefore used in electro-technology, in lamp stems, in cathode-ray tubes, etc. and are also useful in components used to provide protection from X-rays.

In crystal glasses,  $\text{BaO}$  may substitute part of the  $\text{PbO}$ . Optical glasses are a special subgroup of lead glass.

## Recommendations and Standards

Various recommended procedures have been published by, for example, The International Commission on Glass (in *Glass Technology*) and the American Society of Testing Materials, and in British Standards and German Standards (DIN).

## Analysis of Oxide Glasses

### Samples and Sampling

The hazards of sampling commercial glasses are greatly reduced by the fact that glass as a product of

large-scale melts is generally quite homogeneous. However, care must be taken that the glass sample taken for analysis does not contain faults (striae and stones). Even if the sample seems to be homogeneous, it is possible, particularly for products made from a glass containing constituents that volatilize at higher temperatures ( $B_2O_3$ ,  $PbO$ ), that significant differences in composition are observed in different parts of the product.

Samples are crushed to grains of about 5 mm, which are then combined, ground further, and quartered to provide an analytical sample of about 20 g that is then ground to the fineness required for subsequent decomposition. To minimize pick-up of water and carbon dioxide as well as oxidation of some constituents such as iron(II), coarse grinding (60–80 mesh) is recommended, particularly if acid decomposition is to be used. If fusion is planned, a much finer grinding (200–400) mesh is to be preferred.

In order to get correct data on the quantitative content of the glass components in the further course of the analysis, it is first required to determine the humidity of the sample and its weight loss after calcination. The glass sample is placed in the platinum crucible and calcined in the muffle kiln at  $110^\circ\text{C}$  to determine the humidity and then at  $1100$ – $1200^\circ\text{C}$  to measure the weight loss after calcination.

## Decomposition

**Dissolution with hydrofluoric acid** All silicate glasses are decomposed under attack with a mixture of hydrofluoric and other mineral acids. Hydrofluoric acid is very effective because, even at room temperature, hexafluorosilicic acid is formed, which is decomposed at higher temperatures into silicon tetrafluoride and hydrofluoric acid. Both these products are removed from the reaction mixture by evaporation. Some other fluorides ( $BF_3$ ,  $AsF_3$ ,  $SeF_4$ ) are also volatilized.

Glass network modifiers form fluorides and complex fluorides. Heating with a mineral acid such as sulfuric or perchloric acid before analysis will decompose the fluorides formed. Perchloric acid has an advantage because perchlorates are very water soluble, but in the presence of some constituents ( $TiO_2$ ,  $ZrO_2$ ,  $Sb_2O_3$ ), sulfuric acid is preferred. Sulfuric acid cannot be used in the presence of constituents forming insoluble sulfates ( $PbSO_4$ ,  $BaSO_4$ ).

For decomposition of a number of fluorides, it is essential that the fuming step, commonly accompanied by rinsing of the vessel's walls with water, must be thorough and repeated not less than three times. The greater the content of metal(III) and metal(IV)

oxides, the more tenaciously is fluoride likely to be retained in the sample.

The decomposition of glasses with hydrofluoric and perchloric or sulfuric acids is carried out customarily in platinum dishes of  $\sim 100$  ml capacity. Unless hydrogen sulfide, free chlorine, or nitrous oxide is evolved during the decomposition, the corrosion of platinum is negligible.

The sample solution obtained this way serves for the determination of alumina ( $Al_2O_3$ ), iron oxide ( $Fe_2O_3$ ), titania ( $TiO_2$ ), lime ( $CaO$ ), magnesia ( $MgO$ ), and alkali metal oxides.

**Decomposition by alkaline fusion** Fusion with an alkali metal carbonate, usually anhydrous sodium or potassium carbonate or their mixture, decomposes glass samples very effectively. This occurs above the melting point of the carbonate(s):  $Na_2CO_3$ ,  $853^\circ\text{C}$ ;  $K_2CO_3$ ,  $903^\circ\text{C}$ ;  $KNaCO_3$ ,  $712^\circ\text{C}$ . If it is known that the glass does not contain boron, the fusion sample is fused with a mixture of sodium carbonate and borax to decrease the fusion temperature. The complex silicate network is broken down, and monosilicates are formed.

Other anions present are released, and network modifiers form salts corresponding to the acid used finally to dissolve the cold fusion mixture. This reaction is accompanied by evolution of carbon dioxide.

The fusion is carried out in platinum dishes or crucibles. The amounts of the sample and flux depend on the composition of the glass. Customarily, for one part of glass, two to four parts of anhydrous sodium carbonate are used. After dissolution in mineral acid, the solution can be analyzed using various analytical procedures.

**Decomposition for determination of constituents using atomic absorption spectrometry** Weigh 0.1 g of the sample into a small platinum dish. Moisten with a few milliliters of water. Add 2–3 ml of perchloric acid and 5–10 ml of hydrofluoric acid. Transfer the dish to an electrically heated and regulated hot plate, starting at a low temperature. Raise the temperature gradually and evaporate to a slightly moist residue, taking care to achieve a slow rate of decomposition of fluorides because at higher temperatures the decomposition of fluorides is violent and spraying losses may occur. When the perchloric acid has evaporated and the residue is slightly moist, remove the dish, cool, add 1 ml of perchloric acid, rinse the dish walls, and evaporate again.

Rinsing and evaporating with perchloric acid is repeated once or twice for proper removal of fluorides. Moisten the residue with 0.5 ml of perchloric acid, add 25 ml of water, and digest on a hot plate at

~80°C for 10–15 min. Transfer the dissolved residue to a 100 ml volumetric flask, cool, and dilute to the mark. With this procedure a solution of  $1000\times$  dilution is prepared. Other dilutions are prepared from this solution.

### Atomic Spectrometry and Other Instrumental Methods

Modern instrumental methods are used widely in analysis of glasses. First of all, atomic spectrometry and mass spectrometry (MS) should be mentioned.

Qualitative and semiquantitative analysis of glasses having complex composition is performed by atomic emission spectrometry (AES), with the excitation of the spectrum in the direct-current arc. This implementation of AES does not require dissolving the sample and enables one to detect 10–15 elements simultaneously with a detection limit of  $10^{-2}$ – $10^{-4}\%$ . Unfortunately, because of its low precision (10–20%), this method is not suitable for determination of the content of the basic components of glass (glass formers and modifiers). A more universal technique is AES with an inductively coupled plasma (ICP) as a source of atomization and excitation. ICP–AES provides higher detection limits ( $10^{-2}$ – $10^{-8}\%$  for different elements) and precision (1–5%), as well as a wider range of the determined concentrations.

X-ray fluorescence spectrometry (XRF) can be used to determine the content of the basic components of glasses. This multielement analytical technique also does not require dissolving the sample. For a content of 1–100% the precision of the method is not worse than 5%.

Flame atomic absorption spectrometry (AAS) and flame AES are the most commonly used analytical instrumental techniques in analysis of glasses.

The present applications of flame AAS for glass analysis are usually limited to the minor and trace constituents (see Table 1). Although the usual

precision of AAS is 1–2%, by taking special care, a better precision can be achieved as is required for glass analysis. There are some problems with the storage of samples and calibration solutions. They must be stored in the refrigerator below 5°C in polypropylene flasks. After 2–4 months the solutions must be replaced. Great attention must be paid to preparation of the solutions and the quality of the volumetric flasks. Volumes less than 5 ml should not be measured with a pipette; microburettes are recommended. Glass volumetric flasks should not be used as storage flasks because of problems arising from leaching from the glass surface. After measurement the solutions must be transferred to polypropylene flasks or discarded.

Chemical interference occurs, and to suppress such interferences a spectrochemical buffer solution equivalent in amount to 10% of the total sample solution volume is added. Such a buffer contains 1500 µg of lanthanum and 100 µg of cesium in a 1 ml volume.

For evaluation, a direct calibration or a bracketing technique is used. The direct calibration technique is a method for determining the concentration of analytes in the sample solution by reference to a calibration graph produced from a set of calibration solutions having different analyte concentrations (single element calibration solutions) or from a set of solutions having different concentrations of analytes and other elements (multielement calibration solutions). Special care must be given to dilution of the sample and calibration solutions. For normal work a dilution of 0.1 g in 100 ml (1000 times dilution) is used. Calibrating solutions must contain the same concentration of acid as used for dissolving evaporated residues.

Flame AES is used commonly to determine alkali and alkali earth elements in oxide glasses, using the parameters shown in Table 2.

**Table 1** Conditions for determination of elements in glasses by atomic absorption spectrometry

Oxide	Wavelength (nm)	Flame <sup>a</sup>	Maximum linear response range (µg ml <sup>-1</sup> )	Concentration range in glasses (mass%)	Concentration in solution analyzed after 1000-fold dilution (µg ml <sup>-1</sup> )

Flame		Acetylene–air or propane–air	

When analyzing elemental glasses, it is often necessary to determine ultratrace amounts of the elements since practical use of these glasses requires high purity of the material. For example, high purity silica glass used in optical waveguides must include no more than  $10^{-4}$  mass% of most elements. In the analysis of such glasses standard preconcentration techniques are used with subsequent trace analysis of the elements in the concentrate using instrumental methods such as AES, MS, AAS, and XRF. Flame AAS is used most commonly, but techniques such as ICP–MS offer the potential to provide multielement capability and lower detection limits.

The distinctive feature of the above instrumental methods is that they are indirect analytical techniques. They require preliminary calibration using standard samples. The standards must be very close to the analyzed samples in both total chemical composition and physical properties. In this regard these methods are mostly useful for controlling glass production or for analysis of large series of similar samples.

### Determination of Basic Components

**Silica** Silica is the main constituent of the majority of glasses. Successful determination of silica is essential for analysis of glass. This is usually achieved by fusion with sodium carbonate or a mixture of sodium carbonate and borax (2:1) with subsequent dissolution of the cooled melt in 0.1 N hydrochloric acid to avoid polymerization of silica.

In the classical method, the solution is evaporated to dryness, soluble salts are dissolved in hydrochloric acid and hot water, and the system is filtered. The precipitate is transferred to a platinum dish, which is heated to 1100–1200°C and then weighed. The residue is then treated with hydrofluoric and sulfuric acids and evaporated to fumes of  $\text{SO}_3$  and then to dryness and weighed. This process volatilizes silicon as  $\text{SiF}_4$ . The difference between weighings represents the amount of silica.

In modern analytical technique, it is considered that more simple and reliable methods are those using silicomolybdic heteropoly acids. Silica is determined using either a gravimetric or spectrophotometric method. In the first case silica is determined as

silicomolybdic acid quinolate  $((\text{C}_9\text{H}_7\text{ON})_4\text{H}_4\text{SiMo}_{12}\text{O}_{40})$ . The prepared solution ( $\text{SiO}_2 \leq 10$  mg) is mixed under agitation with 10 ml of 10% aqueous solution of ammonium molybdate  $((\text{NH}_4)_2\text{MoO}_4)$  and then with 15 ml of a 2% aqueous solution of quinoline. The precipitate is coagulated in a water bath at 60–80°C, filtered through a Schott filter (grade 4), and dried at 140°C to get the constant weight.

Spectrophotometric determination is performed using UV–visible spectrophotometry with formation of yellow saturated silicomolybdate. The method is used normally for determination of 0.002–1 mg of  $\text{SiO}_2$ . For greater sensitivity (for 0.0001–0.25 mg of  $\text{SiO}_2$ ), the yellow silicomolybdate may be reduced with sodium sulfite or a mixture of citric and ascorbic acids (the solution must contain 5% citric acid and 1% ascorbic acid) to the corresponding silicomolybdenum blue.

Boric oxide increases the apparent amount of  $\text{SiO}_2$  found, but it can be removed before the evaporation is finished by addition of methanol to form volatile trimethylborate. The presence of fluoride decreases the amount of silica found. It can be masked by addition of aluminum nitrate hexahydrate; however, if the fluoride content is greater than 5%, a special procedure must be followed.

**Boric oxide** Boric oxide has a significant effect on the properties of glass and is therefore an important and useful glass constituent. Many other components of glass interfere in its determination; it is therefore necessary to use a separation procedure before the measurement stage, for example, by precipitation of certain metal hydroxides and carbonates.

**Titrimetric determination** The mannitol or glycerol acid–base titration procedure is applied to the dissolved sodium carbonate melt for the determination of milligram amounts of  $\text{B}_2\text{O}_3$ . A blank prepared from a glass that does not contain boric oxide should be subjected to the same procedure. There are certain interferences: the effect of fluoride is eliminated by adding calcium carbonate to the fusion mixture; lead and zinc can be filtered off after dissolution of the melt; phosphate is precipitated by addition of iron(III) chloride. The influence of some interference from such elements as aluminum or titanium can be eliminated by adding ethylenediaminetetraacetic acid (EDTA).

**Alumina** Alumina is almost always present in glasses in amounts varying from tenths of a percent to several percent; in some special glasses the concentration exceeds 10%. Aluminum may be determined gravimetrically as the hydrated oxide or by EDTA

titration. There is the disadvantage that in both methods other constituents ( $\text{Fe}_2\text{O}_3$ ,  $\text{TiO}_2$ ,  $\text{ZrO}_2$ ,  $\text{La}_2\text{O}_3$ ) are determined together with  $\text{Al}_2\text{O}_3$ ; the determined sum of these constituents is reported as sesquioxides,  $\text{R}_2\text{O}_3$ . The individual oxides must be determined separately and the amounts found subtracted from the total  $\text{R}_2\text{O}_3$ . The influence of  $\text{TiO}_2$  can be eliminated by adding  $\text{H}_2\text{O}_2$  to retain titanium in the ternary complex titania-EDTA- $\text{H}_2\text{O}_2$ .

**Lead oxide** Lead oxide is an important constituent of glasses. Other constituents, especially zinc oxide, barium oxide, and calcium oxide, influence the determination of lead oxide in various glasses. Separation of lead oxide using electrolysis to form lead dioxide on the anode and subsequent EDTA titration is a popular method, applied to 50–100 mg of  $\text{PbO}$  after nitric acid-hydrofluoric acid treatment of the glass in a platinum dish.

The solution after electrolytic separation can be used for determination of barium and zinc.

**Alkaline-earth metal oxides** Calcium and magnesium oxides are constituents of nearly all glasses and may be determined using EDTA titration. Neither determination is free of interference.

If the glass contains lead and/or barium oxide, the glass should be treated with a mixture of hydrofluoric and sulfuric acids and the insoluble lead and barium sulfates filtered off before the titration. Lead may also be precipitated with hydrogen sulfide. Small amounts of aluminum and iron may be masked with triethanolamine. Greater amounts of aluminum and iron must be pre-separated by precipitation as their hydrated oxides in the procedure for gravimetric determination of alumina. If the content of iron oxide, alumina, and titania is large, they can be separated using a 25% solution of urotropin.

**Alkali metal oxides** Precise and rapid determination of the alkali metals is essential for controlling glass production because these metal ions have a considerable influence on the properties of glass.

Along with the commonly used flame AES, sodium (50–100 mg  $\text{Na}_2\text{O}$ ) can also be determined gravimetrically through precipitation with zinc uranyl acetate. Potassium may be determined gravimetrically by precipitation with sodium tetraphenylborate. Separation of sodium and potassium in their combined presence can be performed by precipitation of  $\text{KClO}_4$  using perchloric acid. It is possible to determine  $\text{Li}_2\text{O}$  microchemically as hexamethylenetetramine hexacyanoferrate(II) and (III).

**Iron oxide** Iron oxide causes coloration in glass depending on its oxidation state. Iron(II) causes a bluish-green coloration, iron(III) a yellowish coloration. For determination of total iron expressed as  $\text{Fe}_2\text{O}_3$ , a UV-visible spectrophotometric method based on 1,10-phenanthroline is used. Hydroxylamine is used to ensure all the iron is present as iron(II).

## Peculiarities of Analysis of Other Types of Glasses

### Sampling

Standard analytical procedures are used for decomposition of prepared samples of elemental, metallic, halide, and chalcogenide glasses with subsequent determination of the main elements.

For example, sampling of chalcogenide glasses includes treatment of the probe with an aqueous solution of  $\text{NaOH}$  (0.1–17 N) under heating up to  $75^\circ\text{C}$ . The  $\text{NaOH}$  concentration and temperature are selected depending on the particular composition.

### Analysis

The analytical techniques used for metallic and polymer glasses are the same as those used to analyze metallic alloys and plastics. Analysis of chalcogenide glasses implies determination of the elements that form these glasses. The peculiarity of the analysis of halide glasses is the necessity to determine chlorine and fluorine.

**Determination of chlorine** Chlorine can be determined in two ways, titrimetrically and spectrophotometrically.

Titrimetric analysis of chlorine is based on the formation of  $\text{HgCl}_2$ . In order to exclude the influence of iron, chromium, and vanadium, 1–2 ml of a 5% solution of hydroxylamine sulfate is added. An ethanol solution of  $0.005 \text{ g ml}^{-1}$  diphenyl carbazone and bromophenol blue is used as an indicator.

Spectrophotometric determination of chlorine is performed at 340 nm as a complex, with a mixed solvent containing  $0.2 \text{ g ml}^{-1}$   $\text{Pb}(\text{NO}_3)_2$  and  $0.1 \text{ g ml}^{-1}$   $\text{AgNO}_3$ . The detection range is from  $0.06 \times 10^{-2}$  to  $0.14 \times 10^{-2} \text{ g ml}^{-1}$  chlorine.

**Determination of fluorine** After dissolution of the prepared glass, the sample fluorine is determined gravimetrically, by precipitating as  $\text{CaF}_2$ , or volumetrically, for example by argentometry after precipitation as  $\text{PbClF}$ , or by titration with a solution of a thorium salt in the presence of alizarin as an indicator. The aliquot of the analyzed solution must

contain not less than  $1.5 \text{ mg ml}^{-1} \text{ F}^-$ . The interference is from ions that either form stable fluoride complexes or precipitate  $\text{F}^-$ , such as Al, Be, Fe, Zr, Ba, and others. To eliminate their influence, it is required to pre-top fluorine from the analyzed solution as fluosilicic acid.

## Glossary

Chalcogenide glasses	Glasses formed by sulfides, selenides, and/or tellurides.
Complex glasses (glasses of the mixed type)	Glasses formed by components belonging to different types of chemical compounds.
Elemental glasses	Glasses formed by chemical elements.
Glass	Product of cooling a melt that becomes solid without crystallization.
Glass former	Network former that can form glasses without adding other components.
Halide glasses	Glasses formed by halides (mostly fluorides and chlorides).
Metallic glasses (amorphous metals)	Glasses whose main components are metallic elements.
Modifier	Glass component that facilitates the transition of the main component to the glassy state or significantly modifies the properties of the glass.
Network former	Glass component whose structural units form the continuous glass network.
Organic glasses (optical polymers)	Glasses formed by organic polymers.
Simple glasses	Glasses formed by components belonging to the same type of chemical compound.

## Introduction

Gravimetric analysis is the quantitative estimate of a particular species by measurement of its weight. This is usually achieved by converting the analyte into an almost insoluble compound (precipitate reaction), which can then be weighed directly or can be converted into a stable form and then weighed. Other gravimetric procedures include measurements based on loss in weight of a sample (e.g., determination of moisture content) or gain in weight (e.g., increase in weight due to absorption of gases). Two other types of gravimetric analyses that deserve mention are electrogravimetry and thermogravimetry.

## Precipitation Methods

Many metallic elements in their ionic forms react with negative counterions to produce stable precipitates. Silver ions form stable and highly insoluble salts with chloride, bromide, and iodide. Calcium precipitates quantitatively with oxalate and can be measured reproducibly at any of the three temperature-dependent plateaus as the oxalate, the carbonate, and the oxide. Barium precipitates quantitatively as the sulfate. The reactions often follow the same pattern:

Positive and negative ions in an aqueous solution, otherwise soluble with the counterions in their environment, produce highly insoluble precipitates with certain added reagents.

## Gravimetry Based on Precipitation

Gravimetric analysis by precipitate formation involves a reaction of the following type:

where  $a$  is the number of moles of analyte A and  $r$  is the number of moles of reactant R. The product  $\text{RrAa}$  should be only sparingly soluble in the mother

liquor. This precipitate is filtered off and either dried and weighed or converted into a compound of definite stable composition and then weighed. The reagent may be an organic or inorganic species. Most metals can be precipitated with organic reagents as water-insoluble complexes and can be weighed after filtration and drying. Various techniques are used to ensure that precipitation is complete and to avoid unwanted interferences.

The procedure used for gravimetric analysis based on precipitation thus involves a number of steps:

- preparation of sample solution,
- precipitation,
- digestion,
- filtration and washing,
- drying, ignition, and weighing, and
- computation of results.

### Preparation of Sample Solution

In gravimetric analysis, the solution-preparation step has its own special significance. The analyte must be separated from interfering species, or the interferences must be masked. For example, if iron(III) is to be estimated as its hydrated oxide in the presence of chromium(III), then the mixture is initially treated with perchloric acid so as to oxidize chromium(III) to chromate (chromium(VI),  $\text{CrO}_4^{2-}$ ), followed by addition of ammonia to precipitate the hydrated iron oxide. Sometimes it is necessary to remove interferences, for example, when calcium is to be estimated as calcium sulfate in the presence of barium. The barium is removed as its chromate and the calcium is precipitated quantitatively as its sulfate.

### Precipitation

Precipitation is a critical step in gravimetric analysis because the manner in which precipitation is carried out will decide the particle size and purity of the precipitate. For gravimetric analysis, it is desirable that the precipitate has the following properties:

1. The solubility of the precipitate should be low so that losses from this source are negligible.
2. The precipitate should be able to be filtered and washed easily.
3. The precipitate should be stable and of definite composition.
4. A small amount of analyte should yield a relatively large amount of precipitate, since this

increases the sensitivity of the method. The use of high relative – molecular – mass precipitants (usually organic molecules) is advantageous.

The solubility product,  $K_s$ , of an ionic compound is defined as the product of the concentration of the ions that exist in equilibrium with the solid compound in a saturated solution. Under nonideal conditions activities are used in the place of concentrations. Thus, for an ionic compound  $A_m^{n+}B_n^{m-}$  the solubility product can be expressed in terms of the activities  $a$  of the ions as follows:

$$K_s = (a_{A^{n+}})^m \times (a_{B^{m-}})^n \quad [1]$$

However, when no solid is present, as is the case at the start of a precipitation reaction, the ionic product on the right-hand side of eqn [1] can greatly exceed  $K_s$ . The solution is therefore supersaturated, but it is only when the concentration of solute exceeds the critical supersaturation ratio value that precipitation begins. The critical supersaturation ratio,  $S_{\text{crit}}$ , is defined as the ratio of the smallest concentration needed to bring about the energetically most difficult stage of precipitation, nucleation, to the equilibrium solubility. Nucleation is the formation of a nucleus, the smallest particle of a precipitate that is capable of spontaneous growth.

**Kinetics of nucleation** Nucleation cannot strictly be described as a chemical reaction of a definite order, so that in a nucleation the rate of a reaction is not proportional to a power of concentration *per se*. However, in a restricted concentration interval it is a fairly good approximation to calculate the number of nuclei formed in terms of the supersaturation ratio  $S$ :

$$\ln N = \log K_N - B \left[ \frac{\sigma_{\text{CL}}^3 \nu^2}{k^3 T^3 \ln^2 S} \right] \quad [2]$$

where  $K_N$  is the kinetic constant,  $B$  is a factor depending upon the geometry of the nucleus and the type of crystal growth,  $\sigma_{\text{CL}}$  is the interfacial energy per unit area,  $\nu$  is the molecular volume,  $k$  is the Boltzmann constant,  $T$  is the absolute temperature, and  $S$  is the supersaturation ratio, the ratio of actual concentration to the solubility.

Two types of nucleation have been recognized, heterogeneous and homogenous. Heterogeneous nucleation is a low-energy process that takes place at lower supersaturation and involves impurity particles such as dust, glass fragments. Homogeneous nucleation only involves ions of the precipitate and occurs at higher supersaturation. For example, for barium sulfate  $S_{\text{crit}}$  is 20–30 for heterogeneous nucleation and  $\sim 1000$  for homogeneous nucleation.

**Table 1** Variation of morphological structure of barium sulfate precipitate as a function of supersaturation

Relative supersaturation	Property of precipitate
$7-3 \times 10^5$	Gelatinous
$3-0.75 \times 10^5$	Amorphous and partly colloidal
$5 \times 10^3$	Tiny needles and star-shaped crystals formed immediately
100	Precipitation after 2 h, microcrystalline form
20	Crystalline only after considerable time (1 month)

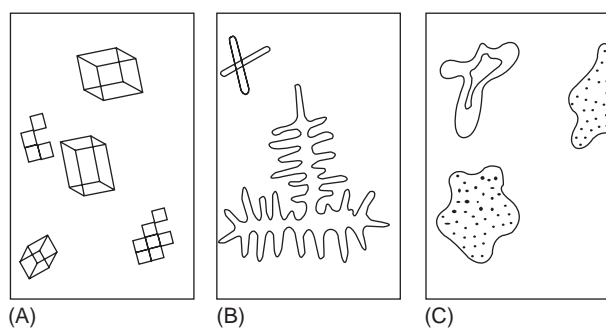

At lower supersaturations, where heterogeneous nucleation takes place, the concentration of the heteronuclei formed is dependent on the concentration of the impurity particles and is not greatly influenced by the ionic concentration, so that particle size increases as the concentration of precipitate ions increases. However, when the supersaturation ratio exceeds that required for homogeneous nucleation to take place, the concentration of nuclei increases rapidly with increasing ionic concentration. At very high supersaturation ratios the increase is so rapid that the ultimate particle size decreases with increasing ionic concentration. **Table 1** shows the variation of the form of barium sulfate precipitate as a function of supersaturation of the solution.

For gravimetric analysis it is desirable that the precipitates obtained can readily be filtered, that is, the particle size must not be too small. Suitable particle sizes are obtained by restricting nucleation to the heterogeneous type. This can often be achieved by using a dilute solution of precipitant and adding it dropwise with stirring. For some precipitates, however, neither of these precautions is successful because homogeneous nucleation occurs even at very low concentrations. This is the case with hydrated iron(III) oxide, which forms a gelatinous precipitate in which colloidal particles are loosely bound by adsorbed ions and much water is held in the structure. Such a precipitate is difficult to filter because it clogs the pores of the filter paper. In such instances, restriction to heterogeneous nucleation can only be achieved by the process known as precipitation from homogeneous solution (see below).

**Particle growth** The rate at which particles grow from nuclei to the final particle size increases with increasing concentration. The slower the growth, the more regular the crystal form and, as described below, the less contaminated is the precipitate.

**Figure 1** shows characteristic crystals of three different forms of barium sulfate. Regular, well-developed crystals are shown in **Figure 1A**, these have

**Figure 1** Characteristic crystals of three different forms of barium sulfate: (A) regular, well-developed crystals formed in a strongly acidic medium at low relative supersaturation; (B) dendritic crystals formed at pH 2–3 and higher relative supersaturation; and (C) gelatinous precipitate obtained from a neutral medium.

been precipitated from a strongly acidic medium with a small relative supersaturation. If the precipitation is carried out at pH 2–3 at a higher relative supersaturation, the rate of accumulation is more rapid than the subsequent redistribution of material in the solid and the structure is dendritic (see **Figure 1B**). The precipitate obtained from neutral solution is barely crystalline because the rate of nucleation and accumulation is so fast (see **Figure 1C**).

**Precipitation from homogeneous solution** Precipitation from homogeneous solution (PFHS), or kinetically controlled precipitation, is a means of avoiding the buildup of high supersaturation by generating the precipitant *in situ* by a chemical reaction. For example, urea may be used as a homogenous precipitant for iron(III) or aluminum ions as hydrated oxides. Urea itself is such a weak base that it does not precipitate these species. It hydrolyzes only extremely slowly at room temperature, but does so quite rapidly at 80–90°C. If present in the acidic solution, this results in an increase in pH:

A typical procedure involves adding a suitable amount of urea to an acidified solution of, e.g., aluminum ions. A weak acid, such as formic or acetic acid, is also added to provide buffering action so that the pH does not rise too rapidly as the urea hydrolyzes. The solution is then heated until the pH rises to the desired value, which is  $\sim 4$  for quantitative precipitation of hydrated aluminum oxide. Homogeneously precipitated hydrated aluminum oxide is superior to that precipitated by addition of ammonia in that it is purer, denser, more compact, and more easily filtered. Some reagents used in PFHS are listed in **Table 2**.

**Table 2** Reagents used for PFHS

Precipitant	Reagent	Elements precipitated
$\text{OH}^-$	Urea	Al, Fe, Sn, Ga, Th, Bi
$\text{PO}_4^{3-}$	Trimethyl phosphate	Zr, Hf
$\text{C}_2\text{O}_4^{2-}$	Ethyl oxalate	Mg, Zn, Ca
$\text{SO}_4^{2-}$	Dimethyl sulfate	Ba, Sr, Ca, Pb
$\text{CO}_3^{2-}$	Trichloroacetic acid	La, Ba, Ra
$\text{H}_2\text{S}$	Thioacetamide	Sb, Mo, Cu, Cd
Dimethylglyoxime	Biacetyl + hydroxylamine	Ni, Pd

**Contamination of precipitates** Precipitates usually contain impurities. Such contamination mostly occurs during precipitation and the phenomenon is known as co-precipitation. Some contamination may occur after precipitation, i.e., on the surface of the final particles.

Co-precipitation causes contamination throughout the body of the precipitate if the particles or impurity ions or molecules are present during precipitation and are incorporated into the crystal structure of the precipitate particles throughout their growth. If precipitation is slow, the amount of co-precipitation is governed by the relative solubilities of the compound concerned, but with an increase in speed of precipitation the relative amount of co-precipitation also increases. For this reason, PFHS is advantageous for producing purer precipitates. Digestion of the precipitate, i.e., heating it for a time in the precipitation medium, causes some expulsion of foreign species, if there is any temporary dissolution of the precipitate, but some contamination will remain. Some of the mother liquor may also be occluded during rapid precipitation.

Co-precipitation on the surface of the precipitate is particularly important for precipitates of large surface area, e.g., gelatinous precipitates. It is essentially an adsorption effect, because the amount of contamination is the same whether the contaminating ions are present during precipitation or added afterwards. Digestion of the precipitate does not decrease the amount of adsorption because the surface area of gelatinous precipitates is not greatly affected by such treatment. Moreover, such contamination is essential for the precipitate to retain its gelatinous structure and not disperse as a colloidal suspension. However, a purer precipitate can sometimes be obtained by appropriate treatment, e.g., when silver is precipitated as its chloride, washing the precipitate with dilute acid will replace all the adsorbed potassium ions with hydrogen ions, which then volatilize as hydrochloric acid when the precipitate is dried.

### Digestion

The process of digestion is usually carried out by allowing the precipitate to remain in contact with the mother liquor, generally at a high temperature, for some time before filtration. By doing so complete precipitation is ensured and the smaller particles, which have higher solubility, tend to dissolve and make the solution supersaturated with respect to large particles. To restore the solution equilibrium, the dissolved material deposits on the larger particles, a process known as Ostwald ripening. A similar process applies to irregularities in the crystal structure. Protrusions are more soluble than cavities, and so are dissolved and precipitated in cavities, making the precipitate more regular. This is known as internal ripening. The net result of digestion is to improve the filterability of the precipitate, and also its purity since impurities may be released from the crystal structure on temporary dissolution.

### Filtration and Washing

Depending upon the nature of the precipitate and its subsequent treatment, filtration is carried out in different ways. If the precipitate is to be ignited, then it is generally filtered through a special type of ashless filter paper having a specified pore size chosen to retain the precipitate completely. If the precipitate is to be weighed after drying without any other treatment, then it is filtered on a special type of sintered bed. The precipitate is retained on the bed, which is dried and weighed.

Most precipitates are contaminated with one or more soluble compounds. The washing process is used to remove these as completely as possible. The composition of the washing solution chosen will depend upon:

1. the solubility and chemical properties of the precipitate;
2. the tendency of the precipitate to form a colloidal suspension (peptization);
3. the nature of the impurity to be removed; and

4. the effect of residual traces of the washing solution on the precipitate in the subsequent stages of drying/ignition.

Water often cannot be used because of the possibility of peptization of the precipitate, and also because of small losses arising from slight solubility of the precipitate. A solution of a suitable electrolyte is therefore generally used. The electrolyte chosen should possess an ion in common with the precipitate to suppress solubility and it should be easily volatilized when the precipitate is heated prior to weighing.

### Drying, Ignition, and Weighing

After a precipitate has been filtered and washed, it must be dried or ignited (heated to a high temperature) to obtain a compound of constant and known composition that can be weighed. The term drying is used when the chosen temperature is below 250°C and the term ignition used when the temperature range is 250–1200°C. Drying implies removal of solvent, while ignition indicates decomposition of the precipitate to produce a stable weighing form.

**Organic precipitating agents** There are a number of functional groups present in organic reagents that precipitate with metal ions by one of two routes: (1) chelating agents are organic compounds that ‘wrap around’ a metal ion due to cationic side chains that form coordinate bonds with the ion, and (2) a straightforward ion–ion bond that produces a new species that excludes water of solvation and thus the product precipitates. Good examples of chelating agents include oxalic acid, 8-hydroxyquinoline, and dimethylglyoxime.

Some common organic precipitating agents are given in Table 3.

**Inorganic precipitating reagents** Most inorganic ions have yielded to gravimetric analytical techniques, but one finds many interfering ions. Table 4 illustrates both the abundance of reagents available

**Table 3** Organic precipitants used in gravimetric analysis

Compound	Ions precipitated
Dimethylglyoxime	$\text{Ni}^{2+}$ , $\text{Pd}^{2+}$ , $\text{Pt}^{2+}$

for use as well as the problems that can be encountered from interfering ions.

### Gravimetric Determination by Weight Loss

Another type of gravimetric determination involves measurement of loss in weight on heating or ignition of a known amount of sample. For example, the sample (analyte) can be hydrogencarbonate ion as shown or a mixture of carbonate and hydrogencarbonate. The total amount of carbonate in whatever form is found by placing the analyte in a solution containing an excess of H<sub>2</sub>SO<sub>4</sub>. This solution is in a flask connected to incoming nitrogen gas gently bubbled through the solution and an exit tube first to a drying agent to absorb aerosolized water and water vapor, and then to a mixture of NaOH and drying agent to absorb the CO<sub>2</sub> and water subsequently produced by the absorption by NaOH:

The apparatus is shown in Figure 2. The tube containing NaOH on asbestos and CaSO<sub>4</sub> to absorb

the final water product is pre- and post-weighed to give the total amount of carbonate in the sample. Note that the nitrogen gas acts only as a carrier and does not take part in any reaction.

### Gravimetric Determination by Weight Gain

A further type of gravimetric determination involves measurement of weight gain. For example, it would be possible to measure the amount of carbon dioxide and water evolved in the reaction described above for conversion of hydrogencarbonate to carbonate by passing the evolved gases through appropriate absorption tubes (a tube filled with anhydrous calcium chloride for absorption of water and a tube filled with potassium hydroxide for absorption of carbon dioxide). The gain in weight is measured and the amount of evolved gas is then correlated directly.

**Electrogravimetry** In electrogravimetry, the analyte is deposited (electroplated) on an electrode under controlled conditions; the increase in the weight is a

**Figure 2** Gravimetric determination by weight loss. (Modified from [www.csudh.edu](http://www.csudh.edu).)

direct measure of the amount of analyte in the sample. The procedure has the advantage that filtration is not required and, if conditions are carefully controlled, co-deposition of other metals can often be avoided. When a current is passed through a solution containing two or more electroactive species, the electrochemical process with the most positive reduction potential will occur first at the cathode. For example, if the solution contains copper, hydrogen, and cadmium ions, copper will deposit first. As the copper deposits the electrode potential becomes more negative until the potential is reached when hydrogen ions are reduced and hydrogen gas is formed at the cathode. The potential at the cathode will remain virtually constant as long as hydrogen gas is evolved, which is usually until all the water is electrolyzed, so that the potential of the cathode cannot become sufficiently negative to cause deposition of cadmium ions. Thus, metal ions with a less negative electrode potential can be separated from those having a more negative electrode potential using the electrodeposition technique.

The electrolytic separation of copper and nickel from cupronickel alloy can be achieved by controlling the pH and electrolytic conditions. Copper is determined in strongly acidic solution at a potential not exceeding 4 V (generally 2–3 V) as above this potential nickel may also plate out. The solution should contain a mixture of sulfuric and nitric acids for complete deposition. However, a high concentration of acid is not recommended as it may lead to incomplete deposition of copper or the deposit may not adhere satisfactorily to the cathode.

The reactions taking place at the respective electrodes are:

At the cathode,

At the anode,

Once all the copper is electroplated, concentrated ammonia is added to the remaining solution (iron if present is precipitated as its hydrated oxide and removed by filtration) and nickel is plated on another cathode at 4 A and 3–4 V. The test for completeness of deposition is carried out either by adding water and continuing the electrolysis or by testing with dimethylglyoxime.

**Thermogravimetric analysis** This technique monitors the change in mass of a substance as a function of temperature or time while the sample is subjected to a controlled temperature program.

## Examples of Applications

### Determination of Aluminum in Deodorants

**Sample preparation** For liquid samples, a fixed aliquot is diluted to a known volume and a fraction containing about ~200 mg of aluminum is pipetted out for analysis. For solids or creams a fixed amount is weighed and dissolved in dilute hydrochloric acid and then it is filtered through a fine medium to give a fixed volume.

**Determination** To a fixed volume of a diluted solution add one or two drops of phenolphthalein indicator and dropwise  $2 \text{ mol dm}^{-3}$  ammonia until turbidity occurs. To this solution add  $5 \text{ cm}^3$  of 10% acetic acid and  $10 \text{ cm}^3$  of 8-hydroxyquinoline solution to get a permanent precipitate of the metal complex. Digest and filter through tared Gooch crucible. Wash the precipitate with hot water and weigh after drying at  $120^\circ\text{C}$ . Calculate the amount of aluminum by using the standard molar relationship.

### Determination of Sodium from Dried Plant Powder

Moisten 1–10 g of the sample with sulfuric acid, dry it in an oven, and combust it in a furnace at 500–550°C to destroy the organic matter. Heat the residue on a steam bath with 2–5 cm<sup>3</sup> of concentrated hydrochloric acid, then add ~40 cm<sup>3</sup> of water, and heat till boiling. Add enough 5% CaCl<sub>2</sub> solution to ensure the precipitation of all the phosphates. Check the completeness of the precipitation by making the solution slightly alkaline using ammonia solution. Filter and evaporate to ~5 cm<sup>3</sup>, cool, and add 100 cm<sup>3</sup> of magnesium uranyl acetate solution, place the mixture in a water bath at 20°C, and either stir vigorously or let it stand for 24 h. Filter under suction into a previously weighed sintered bed crucible and wash the precipitate with ethanol saturated with magnesium uranyl acetate solution. Dry at 110°C for 30 min and weigh the precipitate as Na–Mg–uranyl acetate. The amount of sodium can be calculated as

$$\text{Weight of Na} = \text{weight of precipitate} \times 0.0153$$

### Determination of Benzaldehyde in Almond Oil

Weigh a sample containing ~10–50 mg of benzaldehyde in a distillation flask. Add enough ethanol and distil out nearly 100 cm<sup>3</sup> of distillate into a volumetric flask kept in an ice bath. To this distillate add 25 cm<sup>3</sup> of sulfuric acid, mix well, and immediately add 2,4-dinitrophenylhydrazine solution. Heat on water bath for 30 min at 75°C. Then, cool and filter through a previously weighed Gooch crucible. Wash with 25 cm<sup>3</sup> of water and dry at 100°C for 2 h. The amount of benzaldehyde can be calculated from:

$$\text{Weight of benzaldehyde} = \text{weight of precipitate} \times 0.3707$$

### Determination of Copper in Copper Ore

A common example of application of electrogravimetry is the determination of copper. Copper is reduced at potentials more positive than the reduction of hydrogen ion, so it can readily be deposited on a platinum cathode from acidic solutions (see above).

In this experiment, the copper ore sample is first oxidized to dissolve all the analyte. Then the analyte solution is electrolyzed. When the copper analyte is

electrochemically reduced, it deposits on the cathode. The cathode has a large area to allow the reduction of solution phase analyte to take place rapidly and quantitatively. The weight of analyte in the ore is determined by weighing the cathode prior to and after electrolysis.

### Glossary

- |  |  |
|--|--|
| Critical supersaturation ratio ( $S_{\text{crit}}$ ) | The critical supersaturation ratio $S_{\text{crit}}$ is defined as the ratio of the smallest concentration needed to bring about the energetically most difficult stage of precipitation, nucleation, to the equilibrium solubility. Nucleation is the formation of a nucleus, the smallest particle of a precipitate that is capable of spontaneous growth. |
| Co-precipitation                                     | Precipitates usually contain impurities. Such contamination mostly occurs during precipitation and the phenomenon is known as co-precipitation.  |
| Supersaturation ratio ( $S$ )                        | The supersaturation ratio is defined as the actual concentration to the equilibrium solubility.  |

### Iron

Iron has diverse functions in biology and medicine, with the result that both deficiency and excess have severe consequences in humans. Indeed, iron deficiency is the most prevalent nutritional problem in the world today. Most of the iron in the body (on average  $50 \text{ mg kg}^{-1}$  in the adult male and  $40 \text{ mg kg}^{-1}$  in the female) is contained in hemoglobin, which is essential for the transport of oxygen to the tissues. About 15% of the iron is found in myoglobin, which acts as a reservoir of oxygen in muscles. Iron not required immediately is stored in the form of ferritin or hemosiderin, both of which can bind large numbers of iron atoms. A very small proportion of body iron (0.2%) is bound to transferrin, which transports iron between sites of need. The measurement of iron, hemoglobin, and a combination of the proteins described above is necessary for the diagnosis and monitoring of iron deficiency or excess as in hemochromatosis.

Inherited variations in hemoglobin structure exist, some of which have a significantly reduced oxygen-carrying capacity (e.g., sickle-cell anemia and thalassemia). Identification of these hemoglobins is essential for correct treatment. Additionally, the hemoglobin molecule is glycosylated by circulating glucose and the measurement of the proportion of glycosylated hemoglobin in blood has proved invaluable in the monitoring of diabetes mellitus.

### Measurement of Plasma, Urine, and Tissue Iron

Plasma iron is derived mainly from the breakdown of hemoglobin in the reticuloendothelial system. Transferrin reversibly binds iron very firmly – there are no free iron ions present in plasma as they would be very toxic. Molecules of the transferrin–iron complex combine with receptor sites on erythroblasts and are then internalized, releasing iron into the cytosol. Consequently, the first stage in the measurement of iron in plasma (or serum) is dissociation of

the iron from transferrin, either with or without protein precipitation. A number of chemical agents have been successfully used for this process: trichloroacetic acid (TCA), hydrochloric acid, thorium(IV), acetate buffer and heat, and chloroform.

The iron released may be measured using a variety of methods based on two main techniques: atomic absorption spectrometry (AAS) (flame or furnace) and ultraviolet (UV)–visible spectrophotometry. Flame AAS provides the reference method for determination of plasma iron. Protein precipitation with TCA is followed by centrifugation and measurement of iron in the supernatant by the absorption at 248.3 nm in an air–acetylene flame. While atomic absorption methods are routinely used for urine iron measurements, the need to remove protein and any hemoglobin contamination restricts the use of this technique in routine clinical chemistry for plasma iron. Electrothermal atomization AAS methods are typically used for determination of iron in tissues although inductively coupled plasma (ICP) is becoming more widely available.

A number of spectrophotometric/colorimetric methods have been developed for use on the automated analyzers commonly available in clinical chemistry laboratories. These methods typically involve several steps: dissociation of iron from transferrin; reduction of iron(III) to iron(II); formation of colored complexes with iron-chelating chromogens.

Early methods utilized protein precipitation prior to complex formation, while today direct methods predominate. The method recommended by the International Committee for Standardization in Hematology requires protein precipitation with TCA, reduction with thioglycolic acid, followed by complex formation with ferrozine or ferene. Direct methods have significant benefits in analytical rapidity and automation. Dissociation of the transferrin–iron complex may be achieved by means of strong inorganic acids – typically hydrochloric acid – with solubilization of plasma proteins by the use of detergents. The dissociation is facilitated by the presence of a reducing agent, with the added benefit of reducing iron(III) to iron(II) at the same time. A variety of reducing agents have been used including hydroquinone, hydrazine,

**Table 1** Colorimetric reagents for the determination of serum iron, with their wavelength of maximum absorption and their molar absorptivity ( $\epsilon$ ) at that wavelength

Reagent	$\lambda_{\text{max}}$ (nm)	$\epsilon$ ( $\text{mol l}^{-1} \text{cm}^{-1}$ )
2,2'-Bipyridyl	522	8650
1,10-Phenanthroline	510	11 100
2,2',2''-Tripyridyl	552	11 000
Nitroso R salt	720	20 000
Bathophenanthroline	535	22 140
Tripyridyl-s-triazine (TPTZ)	595	22 600
Ferrozine	562	27 900
Ferene-S	593	35 500

sulfite, ascorbic acid, dithionite, hydroxylamine, thioglycolic acid, and mercaptoacetate.

Ascorbic acid is the most commonly used reducing agent. The free iron can then be reacted with a number of iron-chelating agents that form colored complexes. The more common chelating chromogens available are listed in **Table 1** together with the wavelength of maximum absorption and the molar absorptivity. It can be seen that since the discovery of 2,2'-bipyridyl in 1936 there has been a fourfold increase in the sensitivity of the available chromogens. TPTZ and Ferene-S produce blue complexes that have the advantage of being free from interference from bilirubins or the carotenoids, thus obviating the need for a sample blank measurement. These chromogens, however, are not entirely specific for iron as there is some binding and complex formation with copper, which can be removed by incorporating agents such as neocuprine, thiosemicarbazide, or thiourea that preferentially bind copper.

As all the methods mentioned above rely on the measurement of free iron after its release from proteins, iron released from hemoglobin would also be measured. For this reason any hemolysis will lead to falsely elevated plasma iron concentrations.

The reference range for plasma iron in the adult male is  $9\text{--}29 \mu\text{mol l}^{-1}$  with a slightly lower range for females ( $7\text{--}27 \mu\text{mol l}^{-1}$ ). A circadian rhythm has been described for plasma iron, with peak concentrations in the morning and a trough in late afternoon. Plasma iron is typically higher in the neonate, falling rapidly to adult levels, and typically results for the elderly are lower than the adult reference range. Various drugs, e.g., aspirin, allopurinol, and cholestyramine, can cause a decrease in plasma iron concentrations.

### Urine Iron Assays

Urinary iron excretion in normal individuals is relatively low ( $0.08 \text{ mg day}^{-1}$ ), producing concentrations too low to be measured by the methods available for

plasma iron. AAS is the technique of choice for urine iron measurements. Isolated measurements of urine iron concentration are of little clinical value. Clinically, the most valuable measurement is assay of the urine iron excretion after administration of desferrioxamine, an iron chelator. In normal subjects urine iron is elevated up to 10 times the baseline level, while in patients with genetic hemochromatosis elevations of up to 50 times baseline can be seen. Intermediate increases of 10–20-fold may be found in patients with hemosiderosis or following treatment of secondary iron overload from blood transfusions, e.g., in thalassemia patients.

### Tissue Iron

Tissue iron includes iron from heme-containing enzymes of cellular metabolism, accounting for  $\sim 300 \text{ mg}$ , and storage iron of  $800\text{--}1000 \text{ mg}$  in men, with lower amounts in women. The storage iron is predominantly in hepatocytes and in reticuloendothelial cells as ferritin and hemosiderin. Ferritin is located intracellularly and can sequester up to 4500 atoms of iron within its central core. Hemosiderin appears to be an iron-dense material consisting of multiple aggregates of ferritin molecules in which part of the protein shell has been degraded so that the iron cores coalesce. Ferritin is water soluble, whereas hemosiderin is not. Ferritin is widely distributed in liver, spleen, bone marrow, placenta, heart, pancreas, skeletal muscle, and intestinal mucosa. A variety of isoforms exist specific to particular locations, ranging from acidic to basic in nature.

Tissue iron can be visualized and localized on histological sections by the use of Perl's Prussian blue stain, which is based on the reaction of acidic hexacyanoferrate(II) principally with hemosiderin, but also with ferritin. A semiquantitative scoring system has been devised by estimating the iron load in parenchyma cells or Kupffer cells. Quantitative methods utilize both chemical and physical techniques. The tissue is first digested with TCA-HCl at  $65^\circ\text{C}$  for 20 h and the iron in the supernatant is reacted with bathophenanthroline sulfate and thioglycolic acid as in the plasma method. Although suitable for crude assessment of iron status, the precision of the method is less than satisfactory. The most frequently used alternative is AAS after nitric acid digestion. ICP atomic emission spectrometry has been used for assay of liver iron following nitric acid – perchloric acid digestion. ICP-mass spectrometry (ICP-MS) has been used as an online system for the detection of  $^{57}\text{Fe}$  originally incorporated into transferrin. The liver iron was fractionated by liquid chromatography (LC) and the eluate was passed to the ICP-MS system operating with an argon plasma.

Even more exotic techniques such as Mossbauer spectroscopy or electron diffraction measurements have been used in the research environment for detection, identification, and quantification of different forms of hemosiderin.

### Transferrin and Iron-Binding Capacity

Transferrin has two high-affinity binding sites for iron and exists in plasma as a mixture of apotransferrin and the mono- and diferric forms. Transferrin may be measured either directly by immunological techniques or indirectly by its functional capacity to bind iron. The most widely used technique for the measurement of total iron-binding capacity (TIBC) is based on the saturation of transferrin with a solution of iron(III) ions in excess. The excess of iron is removed with an iron adsorbent, usually magnesium carbonate or an anion-exchange resin. The iron concentration in the supernatant is then measured using standard methods for plasma iron. An alternative approach is to measure the unsaturated iron-binding capacity (UIBC). An excess, but known amount, of iron is added and the unbound fraction is measured using a reagent with specificity to unbound iron. The difference between the known and measured amounts of iron is that taken up by the protein. Measurement of UIBC is becoming the more commonly used technique as it does not require manual steps and is more suitable for automation on the large clinical chemistry analyzers.

The reference range for TIBC is typically  $50\text{--}70\ \mu\text{mol l}^{-1}$ . The combination of plasma iron and TIBC measurements can be used to derive the 'transferrin saturation' ( $(\text{plasma iron}/\text{TIBC}) \times 100$ ). In a normal individual transferrin is 30–40% saturated with iron, whereas in anemic subjects the degree of saturation can fall as low as 5%. In patients with hemochromatosis transferrin can be 100% saturated and 'free iron' can be detected in plasma. Pregnancy and oral contraception can increase the TIBC to  $90\ \mu\text{mol l}^{-1}$ .

Most of the common immunological techniques (nephelometry, turbidimetry, etc.) can be used to determine the concentration of transferrin directly. Generally, enhanced turbidimetric assays are now used for transferrin measurements on automated analyzers. Transferrin is decreased in disorders involving reduced or altered protein synthesis (e.g., liver disease) and increased in iron deficiency anemia. A rare condition of near complete absence of plasma transferrin (atransferrinemia) has been reported.

Transferrin has two bi-antennary carbohydrate side chains that can contain up to six sialic acid

residues and the sialylation process appears to be directly affected by excess alcohol intake. Examination of serum from chronic alcohol abusers has revealed that in such subjects there is a greater proportion of asialo-, mono-, and disialo transferrin compared to normal subjects where the tri- and tetrasialo forms predominate. The desialylated forms have been termed 'carbohydrate-deficient transferrin' (CDT) and form the basis of a test for chronic alcohol misuse. The effect of alcohol on transferrin appears to be a direct consequence of alcohol interfering with the sialylation process rather than as a result of any liver damage affecting synthesis as abstinence in alcoholics with liver disease results in the percentage of CDT in plasma returning to normal ( $<2.6\%$ ) within 10–14 days. CDT can be measured using separation techniques such as isoelectric focusing (IEF) or LC where the exact composition of the isoforms can be determined. For routine use in detecting or monitoring subjects misusing alcohol, separation of CDT is usually achieved using microcolumn ion-exchange chromatography with measurement of total transferrin and the carbohydrate-deficient forms allowing calculation of the percentage CDT. This has benefits over absolute measurements as it avoids false negative or positive results in cases of decreased or increased transferrin synthesis (e.g., protein malnutrition or advanced liver disease causing decreased synthesis and iron deficiency or pregnancy causing increased synthesis). A family of inherited diseases is now known in which proteins are deficient in carbohydrate side chains – the carbohydrate-deficient glycoprotein syndromes.

### Serum Transferrin Receptor

The mechanism for the transfer of iron from transferrin to the intracellular compartment of cells is now better understood. A specific transferrin receptor on cell membranes has been identified to which circulating diferric transferrin binds, after which endocytosis of the ligand–receptor complex occurs releasing iron into the cell. In iron deficiency there appears to be upregulation of the transferrin receptors to enable more efficient transfer of iron. The extracellular domain of the transferrin receptor (sTfr) appears to be released into the circulation by proteolytic action during cell turnover and may be detected in plasma (serum) by immunological techniques. Its concentration is increased in iron deficiency anemia ( $18\text{--}35\ \text{mg l}^{-1}$  compared with a normal range of  $3\text{--}9\ \text{mg l}^{-1}$ ). Measurement of sTfr is beneficial for distinguishing iron-deficiency anemia from the anemia of chronic disease.

### Ferritin

Ferritin consists of a large spherical shell of 24 single protein subunits surrounding an inner core of insoluble iron(III) oxide hydroxide with a portion of iron(III) phosphate. The iron-free protein, apo-ferritin, has a relative molecular mass of  $\sim 450\,000$  that can double when fully saturated with iron. Ferritin is measured immunologically with isotopic or nonisotopic (enzyme or chemiluminescence) immunoassays. In normal subjects there is a wide range of serum ferritin concentrations ( $15\text{--}300\,\mu\text{g l}^{-1}$ ), predominantly due to a highly negative skew to the ferritin results owing to the lower iron stores in women. Ferritin is decreased in iron-deficiency anemia but is an acute-phase protein and may be normal or increased if there is coexisting infection or tissue injury. Ferritin may also be produced by a number of malignant tumors. A ferritin greater than  $750\,\mu\text{g l}^{-1}$  in the absence of an acute phase is indicative of iron overload and if secondary causes can be excluded, genetic hemochromatosis should be considered. The disease causing mutation for hemochromatosis (C282Y mutation in the HFE gene) is now known and can be detected using PCR and restriction enzyme digest methods.

### RBC Zinc Protoporphyrin

In iron deficiency where iron is unavailable for incorporation into heme in the developing reticulocytes or where incorporation is inhibited as in lead toxicity, protoporphyrin IX accumulates in the red cells. This can be measured by extraction into ethyl acetate–acetic acid and then back-extracted into HCl. After neutralization, an ether extraction followed by differential extraction into HCl allows separation of protoporphyrin and coproprophyrin.

### Hemoglobin

Iron is incorporated into the heme produced by the porphyrin synthetic pathway by linkage to the four nitrogen atoms of protoporphyrin. In hemoglobin, four heme units are linked to four polypeptide chains, consisting of two pairs of like chains. There are four major types of hemoglobin (A, A<sub>2</sub>, F, and G) with chain structures:

- HbA 97% of total Hb in an adult =  $\alpha_2\beta_2$ ,
- HbA<sub>2</sub> 3% of total Hb in an adult =  $\alpha_2\delta_2$ ,
- HbF fetal Hb =  $\alpha_2\gamma_2$ , and
- HbG intrauterine Hb = G1  $\xi_2\varepsilon_2$  and G2  $\alpha_2\varepsilon_2$ .

Disorders of hemoglobin resulting from structural abnormalities of a globin chain are termed

hemoglobinopathies, with over 400 variants known, the majority of which are clinically benign. The separation of these variants will be discussed later.

The measurement of total hemoglobin concentration in blood is one of the most frequently requested tests in medicine. Automated methods predominate but the principle of the method is little changed from the original manual techniques. The Fe(II) of hemoglobin is oxidized to Fe(III) by the addition of hexacyanoferrate(III) and then converted into stable cyanmethemoglobin by the addition of potassium cyanide. The absorbance of cyanmethemoglobin is measured at 540 nm. The normal range for adult males is  $14\text{--}18\,\text{g dl}^{-1}$  and for females  $12\text{--}16\,\text{g dl}^{-1}$ .

### Hemoglobin Derivatives

The function of hemoglobin is the transport of oxygen to the tissues from the lungs. When oxygen is associated with the molecule it is termed oxyhemoglobin (OHb), whilst in the absence of oxygen it is termed deoxyhemoglobin or reduced hemoglobin (RHb). In these forms iron is present as iron(II). When the iron is present as iron(III), a brown pigment is formed – methemoglobin. If carbon monoxide is present, i.e., because of smoke inhalation, a hemoglobin–carbon monoxide complex is formed that is referred to as carboxyhemoglobin (COHb). A final derivative of clinical interest is the degradation product sulfhemoglobin (SHb) that contains one more sulfur atom than normal hemoglobin. The iron is in the iron(II) state but the binding of oxygen is inhibited.

For the assessment of the oxygenation state of a patient, measurement of the proportion of oxyhemoglobin can be of value and a variety of commercial instruments exist for the measurement of the hemoglobin derivatives (oximeters, co-oximeters, and hemoglobinometers). The hemoglobin derivatives have differing absorption maxima (Figure 1) and these instruments are based on the differential spectroscopic measurement of the main derivatives: OHb, RHb, and COHb, plus in some cases SHb. The absorption maxima are known to vary with temperature and most commercial instruments are fitted with a temperature-controlled cuvette. COHb normally constitutes less than 5% of total hemoglobin, although this may be slightly higher in heavy smokers. COHb concentrations greater than 20% from smoke or carbon monoxide inhalation are usually fatal unless treated by the use of a hyperbaric oxygen chamber.

The normal concentration of methemoglobin is 1.5% of total hemoglobin, although in congenital methemoglobinemia due to methemoglobin reductase deficiency this may increase to 10–20%. Methemoglobin

**Figure 1** Absorption spectra in the region 500–650 nm of the main hemoglobin derivatives: reduced hemoglobin (---), oxyhemoglobin (—), carboxyhemoglobin (-.-), and methemoglobin (.....). (Reproduced with permission from Instrumentation Laboratories 482 co-oximeter manual.)

can be measured by its absorbance in the region of 630–635 nm, which is eliminated by the addition of cyanide. Sulfhemoglobin is not a normal constituent in blood but may be present owing to reaction to certain drugs, e.g., phenacetin. Sulfhemoglobin has a broad absorbance band in the region of 600–620 nm that is not destroyed by cyanide.

### Separation of Variant Hemoglobins

The best-known hemoglobinopathies are sickle-cell anemia and thalassemia, which manifest clinically as a chronic anemia, hemolytic in the former and microcytic in the latter. Sickle cell disease is found predominantly in people of African descent and is characterized by sickle-shaped erythrocytes due to the homozygous inheritance of HbS in which valine is substituted for glutamic acid at position 6 in the  $\beta$ -chain. When deoxygenated HbS is much less soluble than deoxygenated HbA and forms rod-like polymers (tactoids), giving the characteristic sickle shape to the red blood cells. Sickling also occurs with HbC, in which lysine is substituted for the same glutamic acid. Thalassemia occurs in subjects of Mediterranean origin or Asian origin and is characterized by defective Hb synthesis. Both  $\alpha$ - and  $\beta$ -thalassemia exist where  $\alpha$ -chain or  $\beta$ -chain synthesis is decreased.

The identification of the variant hemoglobins is based on their separation by electrophoresis or chromatography utilizing the different overall charge on the molecule caused by the amino acid substitutions. Cellulose acetate electrophoresis is normally used for screening and is carried out at pH 8.6, where HbS has two more and HbC four more charges per

**Figure 2** Typical separation of hemoglobin variants using cellulose acetate electrophoresis. Track 1 is a standard mixture of HbA and HbS, tracks 2, 4, 7, 8, 10, 11, 13 are normals; tracks 5 and 6 are HbC traits; tracks 9, 12, 14 are HbS traits; and track 3 is HbS/HbC disease. (Reproduced with permission from the Department of Haematology, King's College Hospital, London.)

molecule than native HbA (Figure 2). Citrate gel electrophoresis at pH 6.2 relies on the interactions of the substituted amino acids with agaroseptin. Those variant hemoglobins with substitutions near the surface, e.g., HbS and HbC, are retained by these interactions while those with deeper substitutions, such as HbD or HbG, are not. Chromatographic techniques use ion-exchange columns (diethylaminoethyl-DEAE cellulose) to separate the variants on the basis of the aforementioned charge differences.

Preliminary screening with cellulose acetate electrophoresis will permit the rapid identification of many variant types of hemoglobin, but for some variants, such as HbD, coelution occurs with HbS. Globin chain electrophoresis can be used to separate these variants. The heme group is dissociated from the globin chain with dithiothreitol and urea followed by cellulose acetate electrophoresis using Tris-EDTA-borate buffer at pH 8.9 and pH 6.2. Excellent resolution of hemoglobin variants can be achieved by IEF. More recently, capillary electrophoresis has been shown to be an effective technique for the separation of hemoglobin variants. Similarly, there is considerable interest in the application of tandem MS to hemoglobin separations.

### Glycohemoglobin and Its Measurement

All the hemoglobin types previously discussed will react with hexose sugars, the product being referred to as glycohemoglobin (GHb). The predominant adult hemoglobin HbA consists of two  $\alpha$ - and two  $\beta$ -chains in a tetramer. Condensation with hexoses gives rise to five GHb derivatives, designated collectively HbA<sub>1</sub>, HbA<sub>1a1</sub>, HbA<sub>1a2</sub>, HbA<sub>1b</sub>, HbA<sub>1c</sub>, and HbA<sub>1d</sub>. *In vivo* condensation between glucose and hemoglobin occurs throughout the lifespan of erythrocytes in proportion to the circulating blood glucose concentration. The GHb concentration in a

particular blood sample therefore reflects the mean blood glucose concentration of the preceding weeks to months. Measurement of GHb has been shown to be a valuable means of monitoring long-term glycemic control in diabetics and is widely used in clinical practice. Since the report of the Diabetes Control and Complications Trial (DCCT) clearly demonstrated a reduction in long-term complications (i.e., nephropathy, retinopathy, and neuropathy) if HbA<sub>1c</sub> is kept below 7.5%, measurements of GHb have been steadily standardized to HbA<sub>1c</sub> DCCT aligned methods.

### Methods for Measurement of GHb

A wide variety of techniques, particularly separation techniques, have been used to measure GHb (Table 2).

**Ion-exchange chromatography** Cation-exchange chromatography, generally involving the use of Biorex 70, has enjoyed widespread popularity for GHb measurements. 'Minicolumns' separate glycated HbA (all fractions) from nonglycated HbA with the hemoglobin concentration in the eluate being measured at either 414 or 552 nm. Although commonly used, these methods suffer the drawback of being sensitive to pH, ionic strength of the buffers used, and the temperature of the column. The results are expressed as HbA<sub>1</sub> with a target range of 6–8% for good glycemic control. Many of these methods are now being standardized to DCCT aligned HbA<sub>1c</sub> values.

**Liquid chromatography** The LC methods are also based on the use of cation-exchange columns. Separation of HbA<sub>1c</sub> from HbA<sub>1a</sub> and HbA<sub>1b</sub> can be achieved using LC and dedicated automated systems are commercially available. A significant disadvantage occurs in populations with a high percentage of abnormal hemoglobins, as to achieve an acceptable throughput a separation time of 5–8 min is used, which is too short to resolve the abnormal hemoglobins, leading to potentially misleading results. Typically, results are expressed as HbA<sub>1c</sub> with a range of 4–6% for nondiabetic subjects.

**Affinity chromatography** Unlike the techniques based on ion exchange, which rely on the small charge differences between the glycated hemoglobins, affinity chromatography utilizes the complex formation that occurs between boronate and the *cis*-diol groups of sugars, particularly fructose. The boronic acid is attached to a support matrix such as agarose and will bind all the species of GHbs. These are then eluted with sorbitol and the hemoglobin quantified colorimetrically. The major advantage of this method is its insensitivity to abnormal hemoglobins and automated versions using LC are available commercially with short cycle times (2–3 min). This method can be used in the clinic setting using capillary blood samples prior to the patient being seen by the diabetologist. Although the affinity chromatography based methods measure all GHb fractions, most are now calibrated to DCCT aligned HbA<sub>1c</sub> values.

**Agar gel electrophoresis** Electrophoresis on agar slabs separates glycated HbA (all forms) from nonglycated HbA as in ion-exchange chromatography but does not suffer from sensitivity to pH, ionic strength, or temperature. The method will not, however, resolve HbF from the glycated fraction, leading to gross overestimation in individuals with persistent HbF. A disadvantage is the analysis time, which even in automated versions, is usually too long for use in a clinic setting.

**Isoelectric focusing** IEF has been used to achieve separation of HbA<sub>0</sub>, HbA<sub>1c</sub>, HbS, and HbC. HbF is also separated but acetylated HbF comigrates with HbA<sub>1c</sub>. Although capable of excellent separation, IEF is too cumbersome for routine use in clinical chemistry.

**Immunoassays** Developments in the production of monoclonal antibodies have led to the production of monoclonal antibodies specific to HbA<sub>1c</sub>. These antibodies have been used with a variety of immunoassay platforms to produce automated methods. Care must be taken to determine if the epitope of the antibody is

**Table 2** Interferences with GHb measurements in the most commonly used techniques

## Introduction

Headspace analysis is a technique for sampling and examining the volatiles associated with a solid or liquid sample. The actual headspace itself is the

volume of vapor or gas above the sample. For most headspace analysis purposes the sample and its associated headspace are held within an enclosed container (**Figure 1**). Often, it is the volatiles that are of primary importance when, for example, the chemical composition of the mixture giving rise to the aroma of the sample is to be determined. In other circumstances, examination of the volatiles rather than the whole sample greatly simplifies the analysis and still gives information relating to the whole sample. In effect, the analytical complications that are often apparent as a result of a complex matrix are considerably decreased.

**Figure 1** The fundamental concept of headspace analysis.

## Principles

Headspace volatiles can be examined by a number of analytical methods and, although the technique is most often associated with gas chromatography (GC), it is perfectly feasible for headspace samples to be analyzed by other analytical methods. Such methods as mass spectrometry (MS), molecular spectrometric techniques, and voltammetry have been used, although infrequently and, if the component of interest exists in a volatile form, there is no reason why atomic spectrometry should not be used.

Sampling of headspace vapors at its simplest can be effected by using a gas-tight syringe. In this case a sample of the headspace contained in a closed volume above the sample is drawn into the syringe and subsequently introduced into the analytical instrumentation. Alternatively, an automated system can be used in which the sample can be conditioned in various ways according to the capabilities of the instrumentation prior to introduction into the analytical system using autosampler syringe technology or a sample transfer line. The results obtained depend upon the analytical technique chosen to supplement the headspace sampling procedure.

Static and dynamic headspace sampling techniques may be distinguished; this is shown diagrammatically in **Figure 2** together with the closely related technique of 'purge and trap'. Static methods involve the removal of a small fraction of the headspace in equilibrium with the liquid. Dynamic methods involve the continuous removal of the headspace sample from above the sample as an enrichment step followed by a concentration of the vapors either cryogenically or using a porous adsorbent. The concentrated sample from the dynamic sampling may then be revaporized (from a cryogenic trap) or desorbed (from a solid adsorbent) and analyzed by an appropriate technique. Less commonly, a headspace sampling technique known as 'continuous flow thin

**Figure 2** Concepts of 'static' headspace (A), 'dynamic' headspace (B), and purge and trap (C) sampling systems.

layer headspace' can be used to concentrate headspace volatiles in a thin layer of a flowing liquid. The concentrate can then be analyzed by the appropriate technique, including those such as voltammetry that are not usually associated with headspace methods.

Qualitative headspace analysis is used in many applications to determine differences between selected samples and to assess the importance of specific compounds in defining the aroma character of certain substances. This approach is often termed 'fingerprinting' as in many instances the composition remains chemically unknown. For additional qualitative data, headspace may be used in conjunction with knowledge of GC retention data or with GC-MS techniques for a more definitive chemical identification.

Quantitative relationships exist between the concentrations of volatiles in equilibrium with liquid samples and these form the basis of quantitative theory for headspace techniques. The partition coefficient,  $K$ , is the parameter of fundamental importance and it is defined as the ratio of concentration of analyte  $a$  in the sample phase  $s$ ,  $C_a^s$  and that in the vapor phase  $v$ ,  $C_a^v$ , at equilibrium (eqn [1]):

$$K = \frac{C_a^s}{C_a^v} \quad [1]$$

The sensitivity of headspace analysis is influenced principally by two sample-related parameters: the partition coefficient of the analyte between the phases and the phase ratio of sample to vapor. Consideration of the mass balance of an analyte in a sample under headspace conditions of equilibrium allows a simple expression to be developed relating sensitivity

to these two parameters (eqn [2]):

$$M_a^o = M_a^s + M_a^v \quad [2]$$

where  $M_a^o$  is the mass of analyte in the original sample,  $M_a^s$  is the mass of analyte in the sample phase under headspace conditions, and  $M_a^v$  is the mass of analyte in the vapor phase under the headspace conditions. This develops to

$$C_a^o V^s = C_a^s V^s + C_a^v V^v \quad [3]$$

where  $C_a^o$  is the concentration of analyte in the original sample,  $V^s$  is the volume of the sample phase, and  $V^v$  is the volume of the vapor phase under headspace conditions.

Incorporating  $K = C_a^s/C_a^v$  from eqn [1] gives

$$C_a^o V^s = K C_a^v V^s + C_a^v V^v \quad [4]$$

and therefore

$$\begin{aligned} C_a^o &= K C_a^v + C_a^v \left( \frac{V^v}{V^s} \right) \\ &= C_a^v \left[ K + \frac{V^v}{V^s} \right] \end{aligned} \quad [5]$$

Now,  $V^v/V^s$  is the phase ratio  $\beta$ , and therefore

$$C_a^o = C_a^v [K + \beta] \quad [6]$$

It is  $C_a^v$  that is proportional to the analytical response, therefore

$$C_a^v = \frac{C_a^o}{K + \beta} \quad [7]$$

Equation [7] shows that for a given concentration of analyte in the original sample,  $C_a^o$ , the analytical response, which is proportional to  $C_a^v$ , will depend upon  $K$  and  $\beta$ . With a large value of  $K$  (e.g., 1000 for ethanol in water), the phase ratio has no influence. Conversely, for a small value of  $K$  (e.g.,  $K \approx 0$  for halogenated species in water), the phase ratio has a significant bearing upon the sensitivity. Chemical methods for modifying the partition characteristics of the system are appropriate in some cases, perhaps the most well known being the addition of salts to the liquid phase to induce a higher concentration of organics in the vapor phase. In addition, the sensitivity of the detector used and the capacity of the analytical system for the sample will influence the sensitivity achievable as it does in any analytical method.

Quantitative analysis using headspace techniques is dependent upon the partition of the analyte between the sample and vapor phases. The concentration of the analyte in the sample phase is usually

the value sought, although it is the vapor phase that is sampled and analyzed. Four different approaches to headspace analysis quantification are discussed below. These are total vaporization, matrix-matched standards of analyte, multiple headspace extraction, and standards addition.

### Total Vaporization

Total vaporization of the analyte into the vapor phase can be realized for a limited number of samples and this provides the simplest case for quantification. As an example, a polymeric matrix containing residual water could be heated to 150°C to effectively drive all the water into the vapor. Headspace analysis of the vapor phase in conjunction with external calibration will give the concentration of water in the vapor phase. From this and knowledge of the vapor phase volume, the total amount of water present in the sample can be calculated. This is expressed in the trivial relationship:

$$M_a^s = M_a^v \quad [8]$$

which becomes

$$M_a^s = C_a^v V^v \quad [9]$$

when the concentration term is introduced, where the terms have the same meanings as given earlier. With a known mass or volume of sample the concentration of analyte in the sample may be calculated.

### Matrix-Matched Analyte Standards

In most practical cases the analyte will be distributed between the sample and vapor phases. Calibration involves preparing standards in a matrix identical to that of the sample with known concentrations of the analyte. The headspaces of these standards are then analyzed under identical conditions to the sample and thereby a calibration graph can be constructed. This procedure is practical for liquids and gives eqn [10]:

$$C_a^s = C_a^{\text{std}} \frac{A_a}{A_{\text{std}}} \quad [10]$$

In eqn [10],  $C_a^{\text{std}}$  is the concentration of analyte in the prepared standard,  $A_a$  is the analytical response to the analyte in the sample, and  $A_{\text{std}}$  is the analytical response to the analyte in the prepared standard. For solid samples, preparation of valid calibration standards is more difficult because the analyte in the real sample may be bound in a different form from that in the standard. These so-called matrix effects are difficult to overcome; however, the method described next provides a viable approach.

### Multiple Headspace Extraction

Multiple headspace extraction is a simple concept. As the headspace is extracted several times from one sample, the analyte concentration is progressively decreased. If the procedure were carried out a sufficient number of times then no analyte would be detected in later extracts. Summing all the values obtained would allow the analyte concentration in the original sample to be calculated. While this procedure would be tedious and time consuming, simpler practical approaches using this concept are available. Multiple headspace extraction is a variant of methods known as stepwise gas extraction and discontinuous gas extraction. Such procedures can be applied to a variety of samples and can be used to quantify analytes in samples for which it is difficult or impossible to set up calibration standards as a result of the matrix complications or difficulties in preparing standards. These methods are therefore particularly valuable for quantification of volatiles in solid samples or for quantifying highly volatile analytes for which the preparation of accurate standards is experimentally difficult.

A series of headspace analyses is carried out on the same sample, which is conditioned to equilibrium between each analysis step. From the progressive, measured decrease in concentrations determined, the analyte concentration in the original sample can be calculated. The theory is outlined below.

With a continuous gas extraction, the decrease in concentration of analyte with time will be proportional to the remaining concentration of analyte (eqn [11]):

$$\frac{-dC_a}{dt} = kC \quad [11]$$

This integrates to give an expression for the concentration of analyte present at time  $t$ :

$$C = C_a^0 e^{-kt} \quad [12]$$

in which  $C_a^0$  is the initial concentration and  $k$  is an exponent that includes the partition coefficient  $K$ . Where concentrations are proportional to the analytical responses of the techniques used, the expression may be transposed to

$$A_n = A_1 e^{(1-n)k'} \quad [13]$$

where concentrations become analytical responses ( $A_n$  is the analytical response of the  $n$ th extraction, etc.) and  $t$  is replaced by the number of extraction steps ( $n$ ) in a multiple sequence having equal time intervals. The new exponent  $k'$  includes contributions from both  $K$  and some instrumental parameters.

From eqn [13], using the mathematics of geometric progression, an expression may be developed to give the

sum of the analytical responses for a series of analyses:

$$\sum A_n = \frac{A_1}{1 - e^{-k'}} \quad [14]$$

in which  $k' = \ln(A_1/A_2)$ . For practical purposes this can be simplified to a procedure involving two extractions, and the sum of analytical responses becomes

$$\sum A_n = \frac{A_1^2}{A_1 - A_2} \quad [15]$$

Further details of the mathematical derivation of these relationships can be found in the texts cited in the 'Further Reading'.

### Standard Addition

Standard addition is also a method commonly used to quantify headspace analysis and can be used in cases where a standard solution of the analyte can be added to the sample in such a way that it exists in an identical form in relation to the matrix as the analyte itself. Analysis of the original sample and the sample with added standard analyte can then provide a value for the concentration of analyte in the original sample.

The analytical response  $A_a$  to the analyte from the sample and the concentration of analyte in the sample,  $C_a^s$ , are related by

$$A_a = K' C_a^s \quad [16]$$

where  $K'$  is a function of the distribution coefficient and the detector response. In a similar way, when a standard is added to the sample to be analyzed the analytical response,  $A_a^*$ , may be expressed as

$$A_a^* = K' \left[ C_a^s \left( \frac{V_a}{V_a + v} \right) + C_{std} \right] \quad [17]$$

in which  $C_a^s$  is the concentration of the analyte in the sample that is to be determined,  $C_{std}$  is the concentration of the standard added,  $V_a$  is the volume of the solution (liquid phase) in which the analyte is dispersed, and  $v$  is the volume of standard solution added (of known concentration).

This expression may be developed to give

$$\begin{aligned} A_a^* &= \frac{A_a}{C_a^s} \left[ C_a^s \left( \frac{V_a}{V_a + v} \right) + C_{std} \right] \\ &= A_a \left[ \left( \frac{V_a}{V_a + v} \right) + \frac{C_{std}}{C_a^s} \right] \end{aligned} \quad [18]$$

$$\frac{A_a C_{std}}{C_a^s} = A_a^* - A_a \left( \frac{V_a}{V_a + v} \right) \quad [19]$$

$$C_a^s = \frac{C_{\text{std}} A_a}{(A_a^* - A_a [V_a / (V_a + v)])}$$

$$= \frac{C_{\text{std}} A_a (V_a + v)}{(A_a^* (V_a + v) - A_a V_a)} \quad [20]$$

This simplifies to

$$C_a^s = \frac{A_a C_{\text{std}}}{A_a^* - A_a} \quad [21]$$

when the volume added as a result of the standard addition is small.

The choice of quantification in headspace analysis therefore depends on the sample and the analyte. Procedures include total vaporization, the use of matrix-matched standards, multiple extractions, and standard additions. A method using an internal standard may be used provided knowledge of the equilibrium constants for the standard and the analyte can be determined.

## Apparatus

The equipment used for headspace analysis in its simplest form may comprise a vial of suitable volume with a septum turn closure through which the sample may be drawn using a gas-tight syringe. With the use of a means of temperature control, this method of sampling headspace volatiles can be effective for simple applications where a qualitative or semiquantitative analytical screening procedure is required.

For more demanding applications, a range of apparatus has been designed for the sampling and

collection of headspace vapors. Commercially available systems exist from several of the major instrument manufacturers (Table 1). Modern equipment is designed for flexibility and can be used for static headspace methods, dynamic sampling, sometimes includes the option of multiple headspace extraction together and a capability to do solid-phase microextraction (SPME) injections. Some equipment is aimed at the electronic nose market for aroma profiling and the identification of odor components. Most manufacturers provide the means for automatic conditioning of samples and provide features to allow vial shaking, constant equilibration times for the sample vials, and method development options whereby the parameters can be progressively changed over a number of samples. Methods for introducing samples into the analytical instrumentation differ from automated syringe technology through sample valve and loop techniques to direct coupling using pressure-balanced sampling.

A wider range of equipment that has particular features for special applications is described in the literature. For example, special apparatus has been designed and reported for sampling the headspace of canned foods and whole cheeses, and from single cigarettes.

## Applications

Headspace techniques have been used for examining a wide variety of samples including environmental samples of soil, water, and air, biological fluids,

**Table 1** Commercially available headspace sampling and injection equipment

foodstuffs and related materials, forensic samples, pharmaceuticals, natural products, and polymers. Such samples are examined to ensure environmental protection, to diagnose medical conditions, to establish compliance with regulations in the food, pharmaceutical, and packaging industries, and for the direct determination of aroma volatiles with their associations to taste and smell. All these applications of the headspace analysis benefit either from the simplification of the analysis by removing some of the matrix effects or as a result of the technique being directly related to the examination of aroma volatiles. As mentioned above, headspace analysis is closely associated with techniques of purge and trap, which also direct attention to the volatiles 'extracted' from a sample by the purge gas.

Environmental samples including soils, water, and air have been examined using various headspace techniques. Soils, estuarine sediments, and industrial wastes have been examined for volatile organics including chlorinated hydrocarbons, benzene, and other aromatics. Groundwater samples have been examined for a wide range of volatile substances including chlorinated hydrocarbons, carbon disulfide, components of gasoline spillages, and methylmercury. The latter analysis was carried out using GC with atomic emission detection. Drinking water has been analyzed for volatile constituents including halocarbons, aromatics, and chloral hydrate using headspace sampling techniques. Dissolved gases and light hydrocarbons have been determined in seawater. In some cases headspace methods give improved limits of detection compared to direct injection procedures, and the problems of column overloading and detector memory effects that can occur with aqueous samples are eliminated. Headspace sampling is also used for determining solvents in waste gases and for a variety of substances in workplace and domestic environments including vulcanization volatiles in the rubber industry, and alkylated benzenes and formaldehyde from particle board products.

Trace components in alcoholic drinks can be determined following headspace concentration procedures, although great care is required to establish that the major components present in the sample are not influencing the partition of the analyte of interest between the liquid and headspace phases.

Volatile components of packaging materials in foods can be detected and quantified using headspace techniques. As an example, vinyl chloride as a component of poly(vinyl chloride) (PVC) has been determined in olive oil after storage in PVC containers.

Analysis of gases associated with fresh food packaging is carried out using a headspace technique, with

instruments being available to determine oxygen and carbon dioxide concentrations using a zirconia oxygen probe and an infrared detector for carbon dioxide.

The requirements for the determination of the impurities present in gases and especially in air are frequently so demanding that direct determination (usually by GC and therefore direct injection) is not feasible. The technique of reverse headspace analysis has been applied to such samples. The gas, the minor impurities of which are to be determined, is equilibrated with a liquid, usually in a special flow cell. The liquid may then be directly injected into a gas chromatograph or, in the case of a nonvolatile liquid being used to trap the impurities, thermal elution of the volatiles can be effective prior to analysis. Such methods have been used to determine sulfur-containing compounds in natural gas and air.

Monomeric residues in polymeric formulations or products can be determined using headspace techniques. Thus, monomeric impurities in aqueous suspensions of polymers for subsequent processing can be determined as a means of reducing possible off-odors in the processed materials. In commercial polymers, monomeric species can be identified and quantified using headspace sampling techniques with the appropriate analytical method. Such monomers may be undesirable with respect to subsequent usage, especially as packaging for food that may then become tainted by the volatile species present.

Clinical samples of urine, blood, expired air, and tissue have been examined using headspace sampling approaches. Thus, chlorinated organic compounds, methanol, acetone, methyl ethyl ketone, and phenols have been determined in urine. Volatile substances in urine have also been used as a guide to acute poisoning, and the determination of stimulants in urine has been proposed as screening test for 'field' use. The determination of the concentration of blood alcohol is the most well-known application of headspace techniques to biological samples. Blood has also been examined for cyanide, methyl sulfide, and formaldehyde levels, the last as a measure of methanol intoxication. The headspace approach for blood samples overcomes the difficulties associated with the alternative direct injection of two-phase samples.

Milk, being a two-phase substance, also creates some analytical difficulties for direct injection methods and therefore headspace techniques have been used to overcome these and to determine the odor components that have a bearing upon milk quality in processing and storage.

Volatiles associated with solids such as polymers and tablet formulations of pharmaceuticals can be

**Table 2** Standard methods using headspace techniques

<i>Application</i>	<i>Standard(s)<sup>a</sup></i>
<i>Determination of residual volatiles</i>	
Residual acrylonitrile content of styrene-acrylonitrile copolymers and nitrile rubber	ASTM D4322
Residual vinyl chloride monomer (ng g <sup>-1</sup> range) in vinyl chloride homopolymers and copolymers	ASTM D4443
Residual vinyl chloride monomer in poly(vinyl chloride) resins	ASTM D3749
Acetaldehyde content of freshly blown poly(ethylene terephthalate) bottles	ASTM D4509
<i>Fire debris samples</i>

determined using headspace techniques. Those samples that dissolve completely can be dealt with as solutions, when the headspace approach allows the volatiles to be analyzed separately from the nonvolatile solids. For insoluble solids the volatiles can be identified but quantification, which has been discussed above, is less straightforward.

Numerous applications of headspace analysis to the determination of the volatile aroma compounds of natural products, their essential oils and extracts have been reported. Thus, fruits, tobacco, hops, mushrooms, and various plants have been examined to determine the volatiles present. Such investigations provide information relating to the important chemistry of aroma, taste, and flavor. This has advanced the understanding of the development of odor in fresh, processed, and preserved food products as well as in flowers, from which fragrances are extracted and developed. Consequently, criteria of quality have been established and an understanding has developed of the changes in volatile composition occurring as a result of aging, storage, and processing procedures. As diverse examples, headspace techniques have been used to examine truffle aroma, volatiles in canned salmon, and from kiwi fruit flowers, and garlic volatiles. Synthesis of nature-identical flavors has been significantly advanced by the results of headspace analysis in this area of aroma and flavor research.

Household and personal hygiene products comprise another group of samples that can be screened and examined for volatile components. Thus, 1,4-dioxane in shampoos, ethylene oxide in cosmetics, and fragrances in soaps and cleaning fluids are examples of typical applications of the technique.

In a small number of selected examples it is possible to use headspace sampling techniques as part of an analytical procedure to determine involatile components in a sample. The headspace sampling usually follows a chemical treatment to produce a volatile compound from the analyte of interest. It is thus possible to determine fluoride in fluorinated milk following initial treatment to produce volatile trifluorosilane.

Headspace techniques are used in a number of standard methods for the examination of a wide variety of samples. Details are given in **Table 2**.

Headspace analysis has largely been neglected in the area of process analysis, although, with the inherent matrix complications that can slow down and complicate such analyses, significant benefits may be realized from such an approach.

Headspace techniques can be used to determine a number of thermodynamically important properties relating to vapor-liquid equilibria. The technique has been used to develop distillation procedures specifically where the selection of solvents in extractive distillation is required. Vapor pressures of pure

substances and activity coefficients may also be determined using headspace techniques.

### Introduction

Purge and trap refers to the technique in which volatile organic compounds (VOCs) are purged out of the sample matrix by an inert gas and carried on to a sorbent trap, where they are concentrated and later introduced into an instrument (gas chromatography (GC) or GC/mass spectrometry (MS)) for analysis. After its introduction in the 1970s, purge and trap quickly gained widespread acceptance, and was adopted by regulatory agencies as a standard method. Today, it is still the workhorse for the analysis of low-concentration VOCs in solids and liquids. The instrumentation and procedures are slightly different for liquid and solid samples. This article discusses its basic theory, instrumentation, operational procedures, quantification methods, and selected applications.

### Theoretical Considerations

Purge and trap is also known as dynamic headspace extraction, which is closely related to static headspace extraction. In both techniques, organic compounds migrate from the sample matrix into its headspace. This is illustrated in Figure 1. In static headspace, equilibrium is reached between the sample and its headspace. In purge and trap, an inert gas is used to continuously remove the analytes out of the sample, thus creating a higher concentration gradient. This enhances the mass transfer of the analytes. Consequently, purge and trap is more sensitive than static headspace analysis. It is suitable for trace analysis with detection limits at parts per billion to

parts per trillion levels. On the other hand, static headspace is often used as a complementarily screening method for high-concentration samples.

There are three main processes in purge and trap: extraction (purging), simultaneous adsorption (trapping), and subsequent desorption (heating). The overall purge-and-trap performance depends on the efficiency of each individual process.

Purging efficiency (the percentage of analytes removed from the sample) depends upon the properties of the analytes, purge temperature, flow rate, duration of the purging, and sample matrix. Purging is most efficient for VOCs that are insoluble or

**Figure 1** Comparison of purge and trap with static headspace extraction. (A) Static head space and (B) purge and trap.

substances and activity coefficients may also be determined using headspace techniques.

### Introduction

Purge and trap refers to the technique in which volatile organic compounds (VOCs) are purged out of the sample matrix by an inert gas and carried on to a sorbent trap, where they are concentrated and later introduced into an instrument (gas chromatography (GC) or GC/mass spectrometry (MS)) for analysis. After its introduction in the 1970s, purge and trap quickly gained widespread acceptance, and was adopted by regulatory agencies as a standard method. Today, it is still the workhorse for the analysis of low-concentration VOCs in solids and liquids. The instrumentation and procedures are slightly different for liquid and solid samples. This article discusses its basic theory, instrumentation, operational procedures, quantification methods, and selected applications.

### Theoretical Considerations

Purge and trap is also known as dynamic headspace extraction, which is closely related to static headspace extraction. In both techniques, organic compounds migrate from the sample matrix into its headspace. This is illustrated in Figure 1. In static headspace, equilibrium is reached between the sample and its headspace. In purge and trap, an inert gas is used to continuously remove the analytes out of the sample, thus creating a higher concentration gradient. This enhances the mass transfer of the analytes. Consequently, purge and trap is more sensitive than static headspace analysis. It is suitable for trace analysis with detection limits at parts per billion to

parts per trillion levels. On the other hand, static headspace is often used as a complementarily screening method for high-concentration samples.

There are three main processes in purge and trap: extraction (purging), simultaneous adsorption (trapping), and subsequent desorption (heating). The overall purge-and-trap performance depends on the efficiency of each individual process.

Purging efficiency (the percentage of analytes removed from the sample) depends upon the properties of the analytes, purge temperature, flow rate, duration of the purging, and sample matrix. Purging is most efficient for VOCs that are insoluble or

**Figure 1** Comparison of purge and trap with static headspace extraction. (A) Static head space and (B) purge and trap.

slightly soluble in water. Purging at ambient temperature is adequate for these compounds. Water-soluble VOCs (e.g., ketones, alcohols, aldehydes, and some ethers) are more difficult to purge, and detection limits can be an order of magnitude higher if purged under the same conditions as those for the nonpolar VOCs. Purging efficiency can also be improved by using elevated temperatures. Acceptable recovery can be obtained for many water-soluble compounds when purged at 80°C. Purge time has traditionally been set as 11 min and is rarely used as a variable. For most compounds, the optimum flow rate is in the range of 20–40 ml min<sup>-1</sup>. High flow rates can improve the recovery of compounds that are hard to purge. Very low flow rates should be avoided for such compounds (e.g., bromoform). At high flow rates, however, gaseous compounds (boiling point lower than 35°C, e.g., chloromethane) can be lost from the trap due to breakthrough. Thus, excessively high flow rates should be avoided. Although matrix effects are generally not an issue for relatively clean samples such as drinking water and groundwater, they are not uncommon for complex samples such as soils, sludges, foods, and polymers. Appropriate quantification methods that can compensate for the matrix effects should be used accordingly.

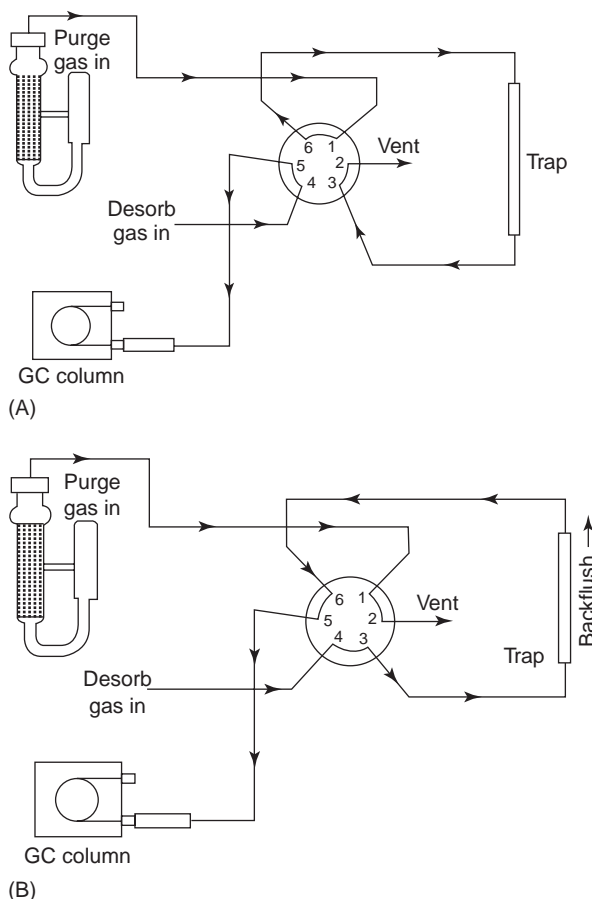

Trapping efficiency is dependent on the properties of the target compounds and the sorbent materials used in the trap. Generally, compounds with lower boiling points are more difficult to trap, and require the use of stronger sorbents. Trapping is also more efficient at lower temperatures. For most compounds, ambient temperature is adequate.

Desorption efficiency is affected by temperature, trap heating rate, and desorb-gas flow rate. Analytes are released faster at a higher temperature, which is limited by the thermal stability of the sorbent materials. Also, the faster the trap is heated, the shorter the desorption time. In addition, desorption is more efficient at higher flow rate. The actual flow rate depends upon the GC column used.

## Instrumentation

Figure 2 shows a schematic diagram of a typical purge-and-trap system. It consists of two major components: a purging device and a sorbent trap. The two parts are connected with each other and to the analytical instrument through transfer lines, with a six-port switching valve controlling the flow path.

Three types of purging vessels are commonly used: frit spargers, fritless spargers, and needle spargers. The frit creates fine gas bubbles with large surface areas, which facilitate mass transfer of analytes into

**Figure 2** Schematic diagram of purge and trap: (A) purge mode – valve positioned to purge sample onto trap; (B) desorb mode – valve position rotated to desorb sample from trap and onto the GC column. (Courtesy of Restek Corp., used by permission.)

the gas. Frit spargers (typically 5 or 25 ml) are suitable for relatively clean water samples. The frit can get clogged if sample contains particles, and some sample tends to foam when purged through a frit. Fritless spargers are to be used for these samples. Needle spargers (typically 40 ml) are good for solid samples, which are usually mixed with a liquid before purging.

A trap is typically a 25 cm long tube with an internal diameter of 0.267 cm, and contains one or more layers of sorbents whose trapping abilities range from the weakest at the inlet to the strongest at the outlet. This is shown in Figure 3. During purging, the analyte-laden gas reaches the weak sorbent first, which traps the less volatile compounds. More volatile compounds break through the weak sorbent and subsequently are trapped by strong sorbent. During desorption, the trap is heated and backflushed with the GC carrier gas. In this way, the less volatile compounds never come in contact with

**Figure 3** Schematic diagram of a multilayer sorbent trap, used with backflushed desorption.

strong sorbents, and thus irreversible adsorption is avoided.

Conventional traps typically contain Tenax<sup>®</sup>, silica gel, and charcoal in series, each material filling one-third of the trap. Tenax is a 2,6-diphenylene oxide polymer. It is hydrophobic and has relatively weak trapping ability. It can only trap compounds with boiling points higher than 35°C, and more volatile species and polar compounds are retained poorly. It also has limited thermal stability and is subject to decomposition if heated over 200°C. Silica gel is a hydrophilic sorbent with trapping capacity stronger than Tenax. It is used for trapping compounds that are gases at room temperature (boiling point lower than 35°C). However, water is also retained by silica gel. Charcoal is a very strong sorbent used for trapping the highly volatile species (e.g., dichlorodifluoromethane, boiling point -29°C) that break through Tenax and silica gel. Charcoal is hydrophobic and therefore does not retain much water. The selection of the trap should be based on the target analytes. If only compounds with boiling temperature above 35°C are to be analyzed, silica gel and charcoal can be eliminated and the trap is filled with Tenax.

Alternative sorbent materials that are commonly used include granulated carbon black (GCB or Carbo-pack<sup>®</sup>), carbon molecular sieves (Carbosieve<sup>®</sup>), and Carboxen<sup>®</sup>. These carbon-based materials are hydrophobic. They also have higher thermal stability than Tenax, and can be used at ~245°C. GCB has about the same trapping capacities as Tenax. It is often used in series with Carbosieve or Carboxen, which are strong adsorbents serving as an alternative to silica gel and charcoal.

The transfer lines are usually made of inert materials such as deactivated fused silica, or silica-lined stainless steel tubing. These do not have active sites for adsorption. The lines are heated at ~120°C to avoid analyte condensation. The switching valve is also maintained above 100°C.

Newer instruments usually have a water management system to reduce the amount of water entering the GC. The gas exiting the purge vessel is saturated with water, which is then accumulated on the trap. If not removed, water can enter the GC when the trap is heated. Even at ambient purging temperature, as

much as 11 µl of water can be condensed on the trap and later transferred into the GC during desorption. The amount is significantly more with heated purging. Although water has little effect on analyte desorption from the trap, at a certain level it can cause the deterioration of GC resolution and interfere with the detector (especially photo-ionization detector (PID) and MS). It can also plug the column when a cryogenic interface is used. Therefore, water removal is critical in purge and trap.

There are two approaches for water removal: permeation and condensation. Permaselective membrane (e.g., Nafion<sup>®</sup> tubing) is effective in removing water while retaining the VOCs. However, some polar compounds such as alcohols also go through the membrane along with water vapors. Thus, this method is not suitable for polar analytes. A condensation device is more commonly used. It has less effect on the recovery of polar, water-soluble analytes, although there is always the possibility of losing such compounds. The device is a piece of tubing made of inert material (e.g., nickel). It is placed between the trap and the GC, and is maintained at ~30°C during trap heating, serving as a cold spot in the heated transfer lines. Water is condensed on it and removed from the GC carrier gas. After sample desorption, the device is heated and water vapor is vented. With a state-of-the-art water removal system, the amount of water entering the GC can be reduced to as low as 0.25 µl.

## Operational Procedures

Since purge and trap is hyphenated to GC or GC-MS, its operation must be synchronized with that of the analytical instrument, and the operational parameters of the two units must be compatible. The processing of each sample is a multistep cycle, which includes purge, dry purge, desorb preheat, desorb, and trap recondition/baking. The flow path during each step is controlled by the switching valve, which has two modes/positions: purge and desorb. **Figure 2** shows these two positions and the corresponding flow paths. During the purge-and-trap cycle, the valve is set in the purge position except during the desorb step.

### Purge

An aliquot of sample (5 or 25 ml) is introduced into the purging vessel either using an autosampler or manually using a syringe. The six-port valve is in the purge mode. The purge gas (nitrogen or helium) passes through the sample, purges the VOCs out of the matrix, and carries them to the trap. The VOCs are retained by the sorbents while the gas is vented.

Meanwhile, the desorb gas directly enters the GC. Purge time is typically 11 min at a flow rate of 20–40 ml min<sup>-1</sup>.

Solid samples (typically 5 g) are collected in a vial that contains a magnetic stir bar. Then the vial is sealed hermetically. At the time of analysis, a certain volume (typically 5 ml) of reagent water is added into the sealed vial, and the sample is purged with heating and agitation.

### Dry Purge

After purging, the purge gas bypasses the purging vessel and directly goes to the trap. This is called 'dry purge'. Its purpose is to reduce the water that has condensed on the trap during wet purging. Dry purge typically takes 1–4 min. During this step, the flow path of desorb gas is unchanged. It should be noted that traps containing silica gel are not compatible with dry purge.

### Desorb Preheat

After dry purge, the purge gas flow is stopped. The trap is heated to 5°C below the desorb temperature without gas flow. Preheat makes the subsequent desorption of analytes faster and helps prevent peak tailing.

### Desorb

Following preheat, the valve is switched to the desorb position and the trap is heated to the desorb temperature, which depends upon the type of sorbents. The trap is backflushed with the desorb (carrier) gas at a flow rate compatible with the GC column. The GC run and data acquisition are initiated simultaneously at the onset of desorption (except when a secondary trap is used, see below). Desorption time is typically 2–4 min.

Desorption is fast at a flow rate of ~40 ml min<sup>-1</sup> and this produces a sharp injection for the GC. Packed columns can directly accept such a high flow. Capillary columns offer superior separation capacity than packed columns, but they require lower flow rates. The optimum flow rate for wide-bore capillary columns (0.53 mm ID or larger) is 5–10 ml min<sup>-1</sup> at which desorption is slower. Long columns (60 m or longer) with a thick stationary phase (3 µm or more) can provide adequate retention for highly volatile compounds. For shorter columns, subambient cooling (e.g., 10°C) is often necessary at the beginning of the GC run to retain early eluting compounds. If GC–MS is used, an open split interface or a jet separator is needed to reduce the flow from the GC column into the MS detector.

Narrow-bore capillary columns (0.32 mm ID or smaller) are operated at a flow rate of 2–4 ml min<sup>-1</sup>.

This flow rate is much lower than the optimum flow rate for sample desorption. To solve this problem, two configurations are commonly used. One is to use a high desorb flow rate, which is then split into the GC. However, this also decreases the amount of analytes that enter the GC, leading to decreased sensitivity. The other solution is to desorb at a low flow rate (typically 4 ml min<sup>-1</sup>) for 5 min. Desorption is slow under such conditions and the desorbed analytes need to be refocused. A secondary cryogenic trap is often used for this purpose. It is a piece of uncoated silica tubing cooled to -150°C by liquid nitrogen. Once desorption from the primary trap is finished, the cryogenic trap is rapidly heated to 250°C, and the chromatographic run and data acquisition are started at the same time.

### Trap Recondition

After desorption, the switching valve is returned to the purge position. The trap is baked/reconditioned at (or 5–20°C above) the desorb temperature, and is flushed with purge gas for 8–10 min. The purpose of trap baking is to reduce sample carryover and possible trap contamination. After reconditioning, the trap heater is turned off and purge flow is stopped. Once the trap has cooled down, it is ready for the next sample.

## Methods of Quantification

The most commonly used quantification methods in purge and trap are external standard calibration and internal standard calibration. External standards refer to target compounds of known concentrations that are prepared and analyzed separately from the samples. A calibration curve or calibration factor (CF) is obtained by plotting the peak area count (or height) of the analyte versus its concentration in the standards. The analyte concentration in the sample is equal to its peak area divided by the CF. External standard calibration works well for relatively clean samples where matrix has no or little effects on analyte recovery.

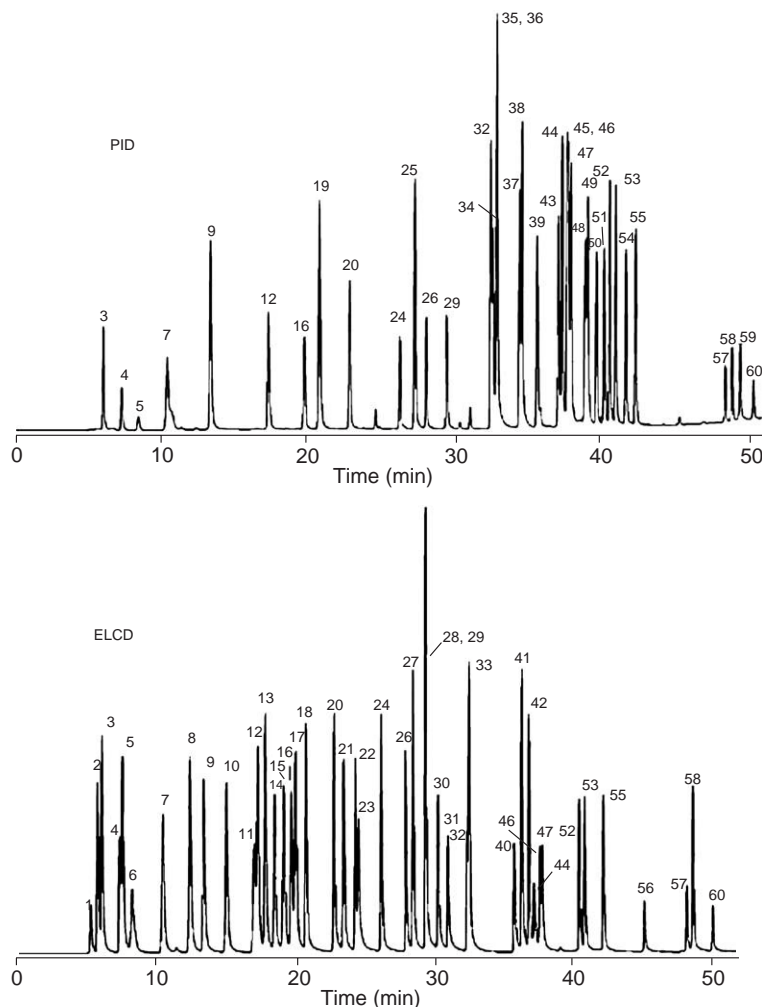

An internal standard is a compound that is not a sample analyte but is similar to the analytes in analytical behavior. It is spiked into each sample and calibration solution at a fixed concentration. The calibration curve is a plot of area ratio of analyte to internal standard versus the analyte concentration in the calibration solutions. The slope of the plot is called the response factor (RF). When a sample is analyzed, the peak areas of the analytes and the internal standard are obtained. The analyte concentration in the sample can be calculated from the area

## Conditions:

Sample: 5 ml of water, 5 ppb each analyte  
 Instrument: O. I. Analytical Model 4560 Purge and Trap  
 Trap: VOCARB® 3000 (Supelco), 10 cm Carboxen® B/6 cm Carboxen 1000/1 cm Carboxen® 1001  
 Purge: 11 min, 25°C, 37 ml min<sup>-1</sup>  
 Desorb: 0.5 min at 220°C  
 Column: VOCOL® (Supelco), 105 m × 0.53 mm ID, 3.0 µm film thickness  
 Oven temperature: 35°C (10 min) to 200°C at 4°C min<sup>-1</sup>, hold  
 Carrier gas: Helium, 8.5 ml min<sup>-1</sup>  
 Detectors: PID (O. I. Analytical Model 5230) and  
 ELCD (O. I. Analytical Model 5220) in series

ratio divided by the RF. The advantage of using internal standards is that it compensates for the variations in experimental conditions such as sample volume and analyte recovery. It is especially desirable for complex samples where purging efficiency varies with matrices. The main limitations of internal standards are that they must not exist in the original sample, and that they must not interfere with the analysis of the target analytes. For environmental samples, fluorinated compounds can be chosen as internal standards since their presence in the environment is uncommon. The use of MS detectors has made the use of internal standard in purge and trap more feasible because internal standards that may coelute with the analytes in a chromatogram can be differentiated by their difference in mass. Stable isotopically labeled compounds are widely used as internal standards in purge and trap with GC-MS. In general, they offer superior precision and accuracy, because these isotope analogs are almost identical to the target compounds in physical and chemical properties, mimicking the behavior of the analytes in every step of the analysis.

## Applications and Trends

Purge and trap has been widely used in environmental, biological, pharmaceutical, food, and other types of analyses. As the determination of volatile pollutants in water and soil remains its most common application, the following offers a description of such an example.

Both water and soil samples can be collected into standard 40 ml volatile organic analysis vials. Commercial autosamplers are available to accommodate multiple (water and soil) samples in the same sequential run. An aliquot of water sample (5–25 ml) is drawn from the vial, and transferred into the sparge vessel. A certain volume of reagent water is added into the soil vial through a syringe without disturbing the hermetic seal. The soil sample is heated and stirred during purging. The selection of the trap largely depends on the target analytes. Each standard and sample goes through the same purge-and-trap cycle described before. Quantitation can be done by using either external standards or internal standards.

Figure 4 shows the experimental conditions and the chromatograms of  $\text{ng ml}^{-1}$  level priority pollutants in drinking water using purge and trap with GC-PID/electrolytic conductivity detector (ELCD). Figure 5 shows a chromatogram of  $\text{ng ml}^{-1}$  level

volatile organics in solid waste by purge and trap with GC-MS.

Purge and trap has undergone significant developments and refinements since its invention nearly three decades ago. Many improvements have come along with the advances in capillary column technology and the widespread use of GC-MS, which have resulted in faster separation, better resolution, and detection. Faster GC analysis calls for faster purge and trap. To that end, commercial automated dual-unit systems have been introduced to increase sample throughput. Although often regarded as a mature technique, advances in purge and trap will continue to reduce cycle time, improve productivity, and find new applications.

## Definition

A herbicide is any individual substance or mixture that is intended to prevent, control, destroy, repel, or mitigate growth of weeds within a crop. Herbicides belong to the pesticide class.

## General Considerations

### Classification

There are many criteria involved in the classification of herbicides, as presented in **Figure 1**. Classifications according to the way of action (**Figure 2**) and chemical structure (**Figure 3**) are to some extent complementary and provide the best comprehensive basis on which the extensive variety of herbicides can be grouped.

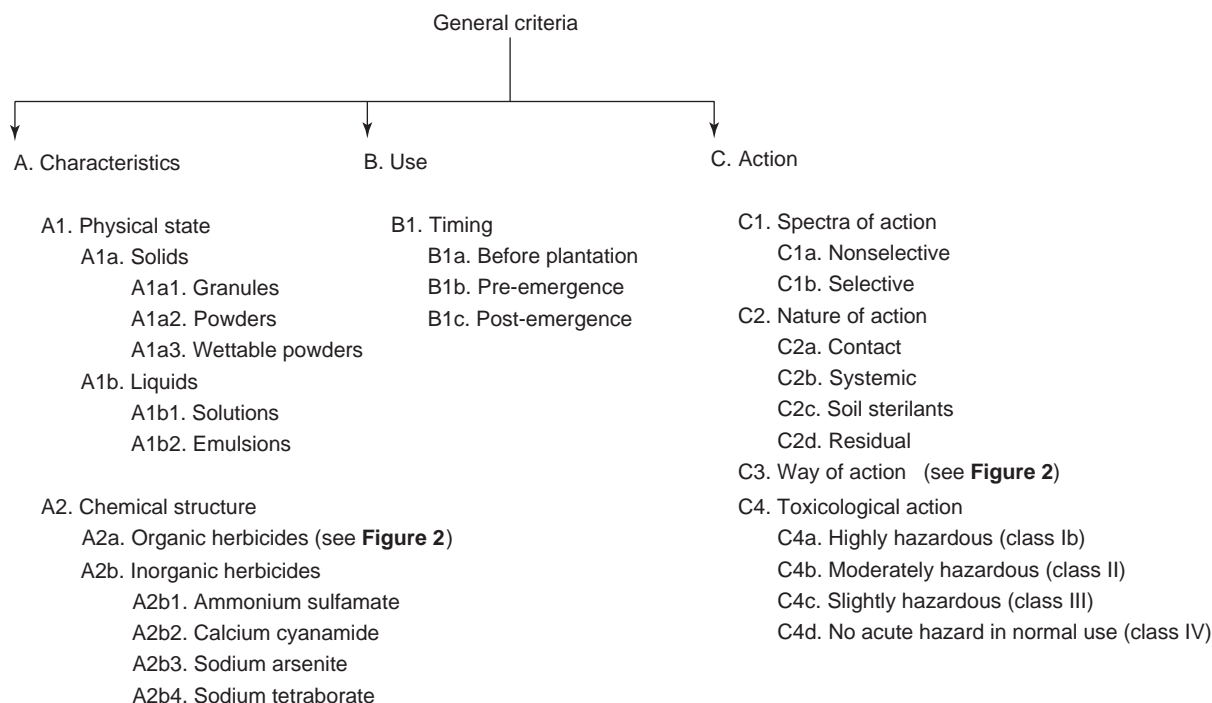

### Herbicide Sources

Herbicide sources are either nonpoint sources or point sources. The nonpoint sources are represented by (1) accidental release on storage; (2) accidental drift during application; (3) surface runoff from land at application points; and (4) leaching through soil. The point sources are represented by (1) direct application points; (2) wastes from manufacturing sites; and (3) spills during mixing, loading, and transportation.

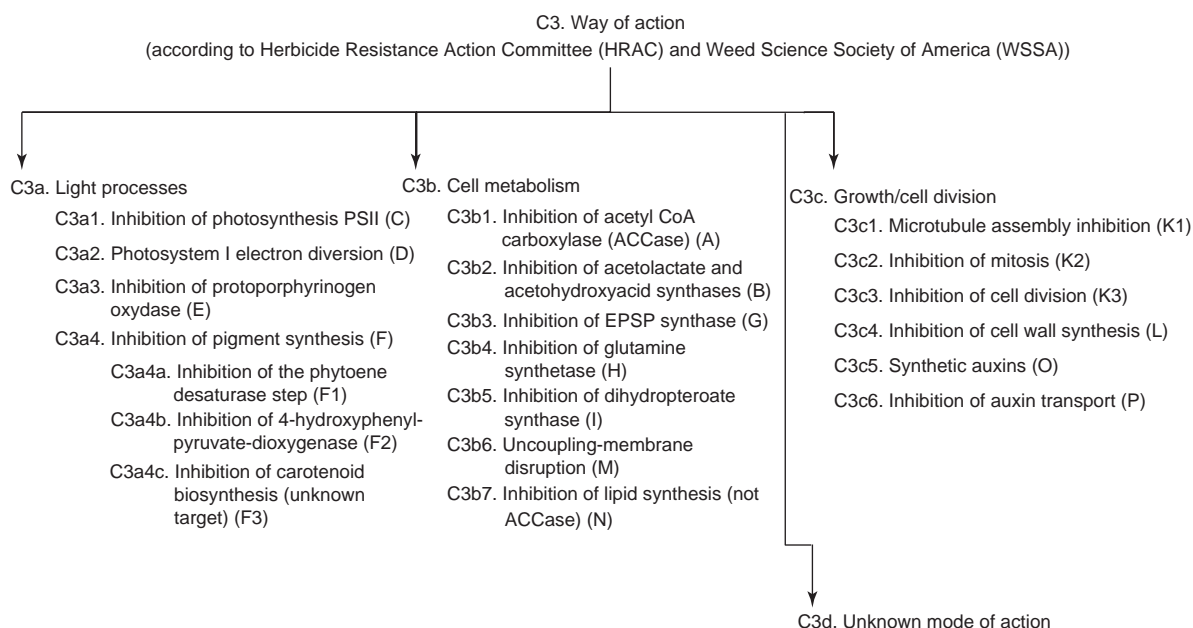

### Herbicide Transport

The transport of herbicides in the environment can be achieved according to the following processes: (1) direct fallout from application points; (2) adsorption on carriers; (3) overland and/or subsurface flow (erosion); and (4) atmospheric deposition (dry or wet).

The migration of herbicides depends on (1) application factors (amount, place, period, frequency, type of formulation, and method of application); (2) persistence and mobility (related to molecular structure and intrinsic physical/chemical properties); (3) soil composition (geomorphology of the application site); (4) geography of the application place; and (5) climate (especially temperature profiles, humidity, rain/storm frequency, and duration).

**Figure 1** General criteria for classification of herbicides.

**Figure 2** Classification of herbicides according to the way of action.

**Figure 3** Classification of herbicides according to the chemical structure.

## Herbicide Effects

Apart from their intended use, herbicides mainly impact on the environment and on human health. Environmental effects should be discussed according to the herbicide toxicity to mammals, birds, fishes, aquatic/soil plants, and microorganisms. The action of the herbicides on human health should be discussed in terms of irritant action, effects on metabolism (uncoupling oxidative phosphorylation, generation of methemoglobin, inhibition of cholinesterase), as well as carcinogenic/mutagenic effects. A rough index of the potential lethal toxicity of a given herbicide is given by the rat acute oral LD<sub>50</sub> dose.

## Herbicide Fate

Most of the lipophilic herbicides tend to undergo enzymatic reactions that make them more water soluble and reactive by the attachment of polar functional groups such as -OH. Most of these reactions are microsomal mixed-function oxidase reactions catalyzed by the cytochrome P-450 enzyme system associated with the endoplasmic reticulum of the cell and occurring most abundantly in the liver of vertebrates. The final products are then involved in conjugation reactions with endogenous conjugating agents (glucuronide, glutathione, sulfate, acetyl) resulting in conjugated species, which have a higher polarity, a greater water solubility, and thus are more easily eliminated.

## Herbicide Persistence

The period of time during which a herbicide remains active in soil at the application area describes its persistence. Its carryover effect describes the presence of the herbicide at the application area once its weed control mission has been accomplished. Transformation processes acting on an herbicide structure are briefly discussed in **Figure 4**. A specific decomposition pattern is illustrated for atrazine in **Figure 5**. Data about degradability and transport of some classes of herbicides are given in **Table 1**. The half-life represents a measure of herbicide persistence and is quantified as the amount of time taken by a herbicide to decompose by 50% from the applied chemical to a herbicidal inactive form. Decomposition products may exhibit higher, reduced, or no herbicidal activity compared to the parent compound, and may exhibit higher, reduced, or no risk effects on environment and human health.

## Herbicide Resistance

The resistance developed by the target weeds to commonly used herbicides over a period of years by

means of natural selection of the occurring biotypes is known as herbicide resistance. Mechanisms for resistance depend on the herbicide's mode of action (e.g., photosynthesis inhibition induced by triazines can be avoided by some weed biotypes by developing slight changes in the chloroplast protein structure). To date, it is known that ~53 species of weeds exhibit resistance to at least five different herbicide classes (e.g., goosegrass and green foxtail to the dinitroaniline congener trifluralin, pigweed and witchgrass to triazines, Russian thistle to the sulfonylurea congener chlorsulfuron).

## Herbicide Market

At present, herbicides are the most widely marketed group of pesticides, including ~267 active compounds formulated in more than 3000 commercial products. The herbicide market in 2001 expressed as a function of the target crop consists of 20% for soybeans and oilseeds, 19% for corn, 17% for cereals, 8% for rice, 6% for fruits and nuts, and 5% for cotton. From the geographic point of view, 40% of the herbicide market is in North America, 25% in Europe, Middle East, and Africa, 18% in Pacific Asia, and 17% in Latin America.

According to the information given in this section, a general characterization file of an herbicide should be presented as given for some examples in **Table 2**.

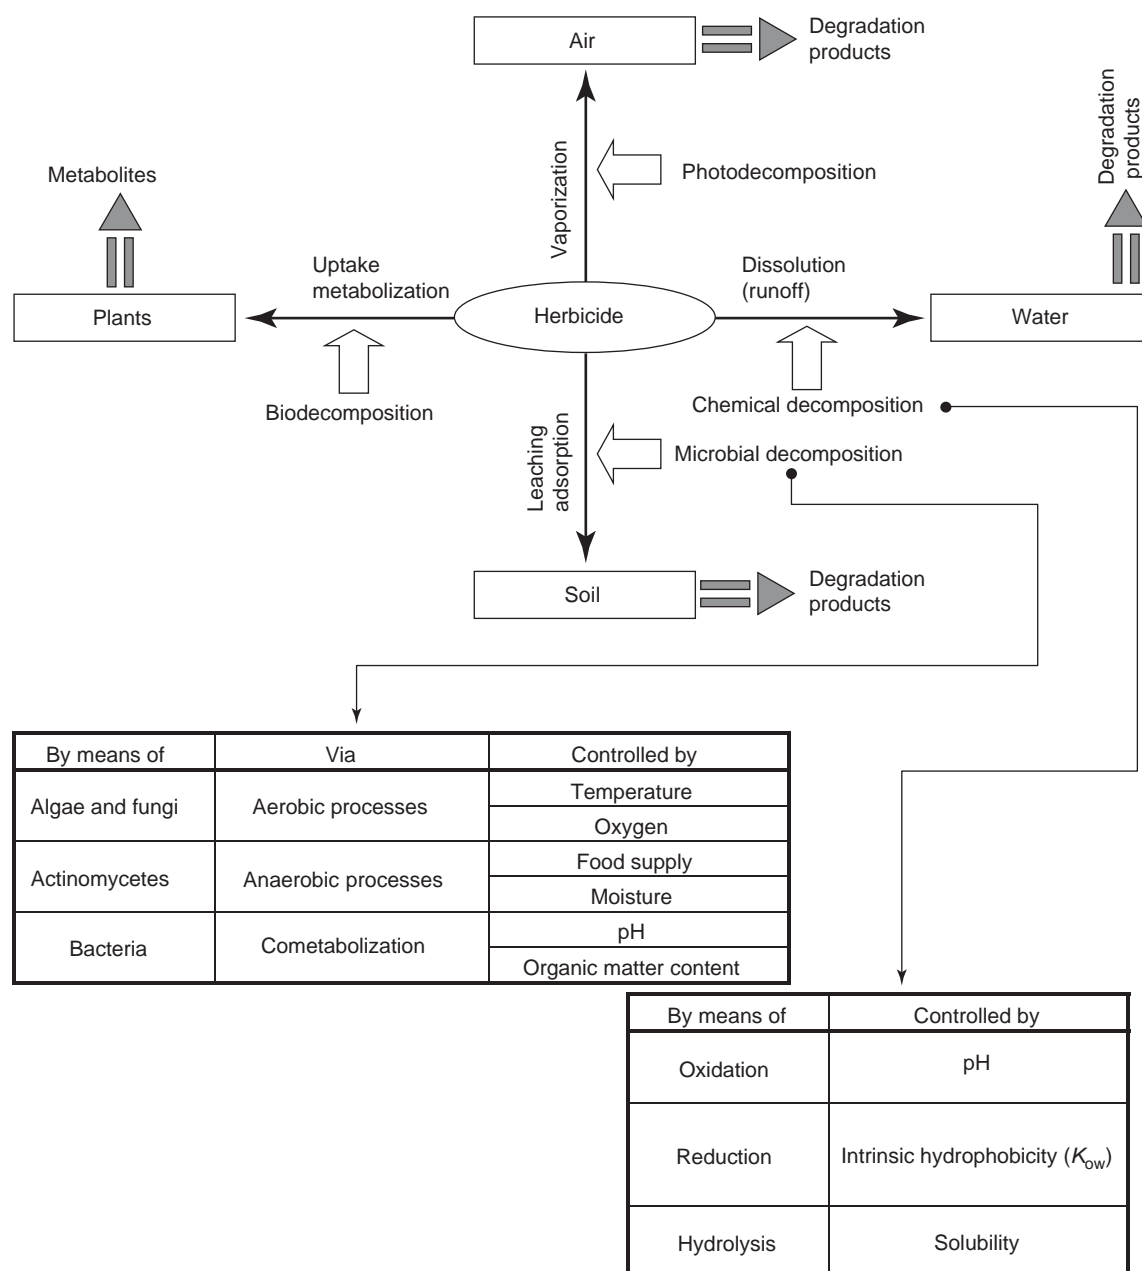

## Herbicide Analysis

The increasing complexity of the chemicals used as herbicides determines the development of more selective and accurate methods of analysis. Basically, analytical aspects related to herbicides should focus on five main directions: (1) quality control of herbicide formulations during production and marketing; (2) research and development for new herbicides; (3) impact on the environment (air, water, soil, and organisms other than humans); (4) impact on food safety; and (5) impact on human health, including forensic aspects.

The targets of the analytical processes are not related only to the determination of the parent compounds. Intermediate synthesis products, breakdown products, and metabolites should also be monitored in more or less complex matrices, sometimes at very low concentrations.

The complexity of the analytical objectives requires not only sensitive and accurate measurements, but, at the same time, correct sampling and sample preservation as well as selective sample preparation methods.

**Figure 4** Transformation processes acting on an herbicide.

## Sampling and Sample Preparation

### Sampling Herbicides

The sampling action should be oriented toward representativity and homogeneity. Sampled quantities should be in accordance with the analytical method further considered and the inherent sensitivity required. Usually, enough material is taken for at least the application of a second full analysis procedure. Traditionally, sampling containers are made of glass. Plastic containers (polyethylene,

polypropylene, or polycarbonate) are often preferred for their robustness. Laboratory tests should be performed prior to the collecting action, in order to demonstrate the suitability of the material of the sampling container. For some particular compounds, adsorption on polymeric materials or even glass may be significant (captan adsorbs readily on glass, while organophosphorus compounds, but not glyphosate, are adsorbed on polyethylene). Mainly for water quality monitoring (environmental analysis) samples may be subjected to concentration at the point of

**Figure 5** Decomposition pattern of atrazine.

L, low; M, medium; H, high.

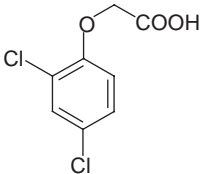

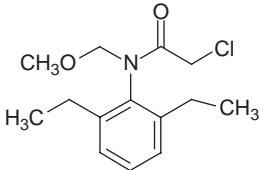

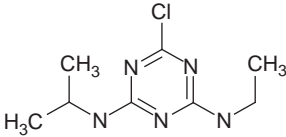

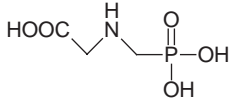

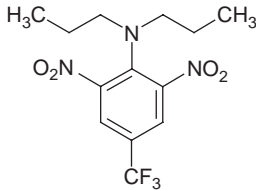

collection. Adsorption cartridges or discs are obtained on the collection site and transported to the laboratory for analysis.

### Sample Preservation and Storage

Preserving sample integrity depends on the stability of the target analytes in a specific matrix. Freezing

samples immediately after collection should provide preservation for thermally unstable extremely volatile compounds. Specific chemical addition of stability enhancing compounds is used occasionally (controlling the pH of the media or blocking active sites of the target analytes by means of derivatization). Contamination and cross-contamination risks should be attentively considered (conditions for transportation

and manipulation of empty sampling containers and collected samples, plasticizers contamination from container walls, etc.).

### Sample Preparation

Sample preparation methods used for herbicide isolation from different matrices are summarized in Figure 6. Some other details are further discussed.

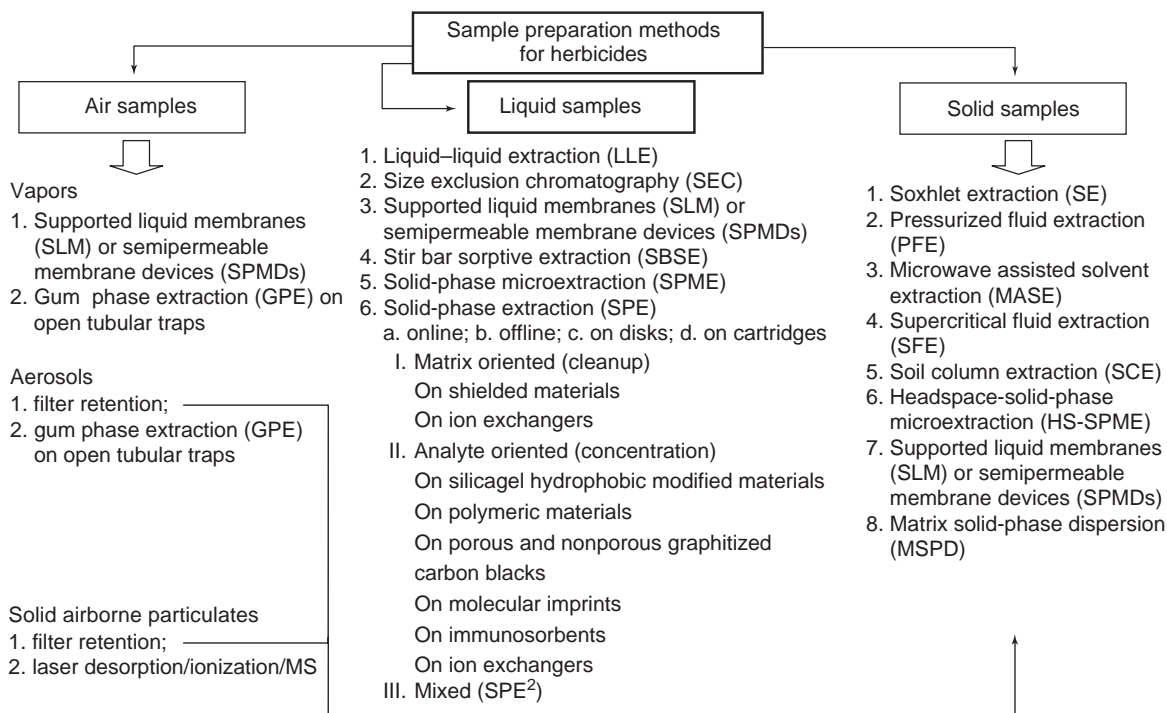

**Liquid-liquid extraction (LLE)** LLE is the classical method used for herbicide isolation, especially from water and biological fluid samples. Ethyl acetate, dichloromethane, and their mixtures are among the preferred extraction solvents for phenylureas, triazoles, amides, carbamates, benzimidazoles, and chlorotriazines. The extraction efficiency is modified by adjustment of pH and ionic strength in the aqueous phase. *In situ* derivatization of the target analytes is also used as an effective tool (e.g., chlorophenoxy acidic herbicides are derivatized with dimethyl sulfate prior to their extraction by n-hexane). The classical way of performing LLE is the separation funnel extraction. Some continuous LLE extractors or steam distillers are also available.

**Solid-phase extraction (SPE)** SPE is used for isolation of the target compounds from liquid media by means of adsorption on a granular solid bed

(cartridge) or on a porous solid membrane (disk). After matrix removal, analytes are desorbed from the solid material using a specific solvent or mixture of solvents. The extract is concentrated by solvent thermal vaporization or gas flush. Direct desorption of the analytes into the liquid chromatography (LC) or supercritical fluid chromatography (SFC) columns by the mobile phase is achievable using an online setup. When using desorption solvents nonmiscible with the solvent of the initial matrix, special attention should be paid to cartridge/disk drying (this operational step is required between sample loading/cleanup and analyte desorption). When using online procedures, it is important to estimate the desorption kinetics of the trapped analytes. Contrarily, serious problems related to analyte focusing and chromatographic efficiency loss may arise.

Four types of adsorbents are usually shared by SPE applications to herbicides. Hydrophobic modified silica materials (C18, C8, C2, C1) are extensively used for a large variety of samples (biological samples such as serum and urine for atrazine, simazine, prometryne, ametryn, sulfonyl ureas, or environmental samples such as different types of waters for alachlor, aldicarb, methiocarb – with concomitant hydrolysis –, medium polar, neutral, and alkaline herbicides, phenyl ureas).

Polymeric materials (styrene-divinyl benzene based copolymers such as PLRP and Lichrolut EN)

**Figure 6** Sample preparation methods for herbicides.

as well as vinyl pyrrolidone–divinyl benzene copolymers (commercially named OASIS) are mainly in current use. These materials behave better than the silica modified adsorbents. They have higher adsorptive properties, allow high volume sample loadings, tolerate alkaline media and larger particles better without any loss of recovery, and are suitable for repetitive use. Special attention should be paid on the desorption step, due to stronger interactions realized between the adsorbent and the trapped analytes. Triazines, ureas, and amidic herbicides are better isolated on the more polar OASIS materials while other compounds including carbamates, thiocarbamates, aryloxypropionic acids, aryloxyphenoxypropionic acids, and related metabolites are well isolated on styrene–divinyl benzene (SDVB) hydrophobic materials.

Nonporous and porous graphitized carbon black solid beds (NPGC and PGC, respectively) are also used for herbicide isolation from water samples. Chlorophenoxy herbicides (requiring online derivatization with tetraalkylammonium salts), acetanilides, neutral diphenyl ethers, triazines, phenyl ureas, triazoles, benzimidazoles, phenoxyalkanoic acids, and quats (paraquat, diquat, difenzoquat) are readily isolated on graphitized carbon beds.

Few applications on herbicide isolation relate to the use of ion exchanging resins. The extraction of chlorophenoxy acidic herbicides residues from green bean samples (2,4-D, MCPA, 2,4-DP, 2,4-DB, MCPB, 2,4,5-TP, and benzoic acid derivative of dicamba) was achieved on hydroxymethylmethacrylate MFE polymer containing quaternary ammonium functional groups. Strong cation exchangers are moreover used for sample cleanup (matrix elimination). Glufosinate and related metabolites in hard water samples and chlormequat in pear, juices, and cereals require matrix cleanup on strong cation exchangers.

Two new directions evolved in the last few years related to the SPE of herbicides: the synthesis of immunosorbents and polymeric molecular imprints. Extraction on immunoaffinity sorbents is based upon the molecular recognition using antibodies. Extraction and cleanup of complex biological and environmental aqueous samples are achieved in a single step even for large volumes. Entrapment of esterases in a ceramic SiO<sub>2</sub> sol–gel matrix leads to isolation of organophosphates and carbamates. Antiatrazine monoclonal antibodies and antidinitrophenyl polyclonal antiserum were also immobilized on the same matrix. Molecular imprints are synthetic polymeric phases on which selective receptors complementary to the target analytes have been generated during preparation. Ethylene glycol dimethylacrylate–methacrylic acid copolymers can be imprinted with

trialkylmelamines or dibuthylmelamine in order to generate templates selective to atrazine. Surface functionalization with molecular imprinted polymers was obtained also for porous polypropylene films. 2-Acrylamido-2-methylpropane sulfonic acid as monomer, *N,N'*-methylbis(acrylamide) as cross-linker and benzophenone as photoinitiator were used in aqueous media for depositing thin films on porous polypropylene. Desmetryn served for producing its own template.

Owing to the increasing complexity of the sample matrices, sequential coupling of two SPE processes (SPE<sup>2</sup>) is sometimes required. Generally, one SPE procedure is addressed to the isolation of the target compounds, while the other acts as a matrix remover (cleanup). A dynamic ion exchange–SPE sequence was applied for the simultaneous isolation of the acidic herbicides and removal of the interfering matrix from environmental waters. The first SPE step is performed on a C18 modified silica gel while the second step is made on an ion exchanging adsorbent. A selective desorption step strongly reduces the interferences of humic acids. Recovery >70% was obtained for chloramben, MCPB, and 2,4-DB using a 0.5 l sample. The same design was applied for analysis of atrazine degradation ozonolysis products. The tandem SPE (on C18 material)/SPE (graphitized carbon deposited on zirconia ZrO<sub>2</sub>) was used for isolation of triazine and carbamates from water samples, while phenolic herbicides were more often isolated on a SPE<sup>2</sup> setup using a SDVB adsorbent in the first step followed by a C1-Hysphere material in the second one.

SPE processes may be subjected to computer assisted optimization. As an example, an orthogonal array design was employed for the optimization of an SPE process applied to atrazine, diazinon, ametryn, and fenthion in surface water. Seven parameters (type of desorption solvent, type of sorbent, flow rate of the elution solvent, sample pH, sample volume, elution volume, organic modifier addition, and flow rate of the water sample) were studied and optimized.

**Solid-phase microextraction (SPME)** SPME consists in the adsorption of the target compounds on a thin polymeric film deposited on the surface of a capillary fiber. The mass transfer can be achieved from liquid media in direct contact with the extracting coated fiber as well as from gaseous environments. Volatile or semivolatile herbicides existing in solid samples can be easily transferred in the gas phase on heating in closed vials, followed by trapping of the resulting vapors in the coated fiber (procedure is known as 'Headspace' HD/SPME).

The nature of the polymeric film as well as its thickness should be related to the polarity characteristics of the extracted compounds. Chloroanilines, sulfamides, phthalimides, and oxazolidones (dichloran, chlorothalonil, vinclozolin, dichlofluanid, captan, folpet, and captofol) were extracted on polyacrylate, polydimethylsiloxane (PDMS), carbowax-divinylbenzene, and PDMS-divinylbenzene films having thicknesses between 30 and 100  $\mu\text{m}$ . Recoveries of the analytes ranged between 70% and 124% when determined in sea water samples. Parameters such as sample pH, ionic strength, organic additives, stirring rates, and contact duration have to be individually considered. Organochlorine herbicides were monitored in landfill leachates using PDMS-coated fibers while ureas (chlorsulfuron, fluometuron, isoproturon, linuron, metobromuron, and monouron) are better isolated on polyacrylate fibers. Trapped compounds can be further thermally desorbed directly into GC inlets, solvent desorbed directly to LC columns, or online/offline desorbed by the supercritical state carbon dioxide for SFC separations.

**Pressure fluid extraction (PFE)** PFE mainly consists of a static or dynamic pressure and temperature assisted liquid–solid extraction. Phenyl ureas from soils and sulfonyl ureas from maize samples were extracted under pressure with methanol at 50°C, using a dynamic setup at 1 ml min<sup>-1</sup> and using a total extractant volume of 25 ml. 2,4-D, 2,4,5-T, dicamba, trichlorpyr, and bentazone have been *in situ* derivatized during the PFE procedure. The variables temperature, pressure, static extraction time, and derivatization reagent amount should be subjected to optimization in order to increase recoveries. Addition of sodium EDTA in the extraction chamber strongly increases 2,4-D recovery.

Water is the most effective modifier of PFE quantitative recovery of chloroacetanilides and triazines in clayey soils. The method requires a pretreatment with 37.6% water after two static extraction cycles with a total of 32 ml of acetone at 1500 psi and 100°C. Extraction time decreases to 22 min (compared to 18 h when using classical Soxhlet extraction) and organic solvent consumption is <80 ml (compared to 300 ml for the same Soxhlet procedure).

An increase of the extraction yield can be obtained by the simultaneous application of a microwave field to the extraction chamber. The resulting procedure is known as microwave-assisted solvent extraction (MASE). Only static procedures are necessary. Atrazine, simazine, terbutometon, terbuthylazine, terbutryn, molinate, and bromacil were extracted from soils by using MASE with methanol, resulting in recoveries >80% for the 5–200 ng per g

concentration interval. Similar results are cited for phenyl ureas.

**Supercritical fluid extraction (SFE)** SFE generally uses supercritical state CO<sub>2</sub> for extracting the target analytes from solid or liquids samples (if liquids are analyzed, adsorption on inert solids is required). The versatility and the enhanced selectivity of the technique relate to the following aspects: (1) the use of the modifiers added to the supercritical state extractant in order to control its polarity; (2) a fully controlled relationship between temperature–pressure–density–solvating power allowing close correlation with the characteristics features of the analytes; (3) the choice of the solid material used for trapping analytes after the supercritical fluid extraction; (4) the choice of the solvent used for desorbing analytes from the solid trapping material; (5) eventual addition of selective adsorbents added to the extraction cartridges acting selectively on the coextracted matrix; (6) either a static or dynamic setup. SFE is used for herbicide analysis in soils and sediments, vegetal materials, foodstuffs, organs, and tissues. Triazine SFE from soils and foodstuffs was extensively studied. The influence of 18 organic modifiers and different solid collectors (florisil produced the best results) were evaluated. A coupled procedure of SPME and SFE for triazines is also available. Interesting applications refers to subcritical water extraction of chlorinated acid herbicides and related esters from soil at 150°C with the *in situ* hydrolysis and online derivatization with trimethylsilyl trifluoroacetamide. The main drawback of SFE lies in terms of the high costs of the equipment and the complexity of the optimization/validation procedures.

**Soil column extraction (SCE)** SCE consists on a specific solvent percolation to a column packed with the sampled material (soil, sediment) containing herbicides. About 100 mmol l<sup>-1</sup> potassium phosphate buffer adjusted to pH 8 at ambient temperature readily extracts imidazolinones, diphenyl ethers, sulfonyl ureas, aryloxyphenoxypionic acids, and triazolopyrimidines from soil samples. The same SCE procedure was applied to 0.2–0.4% carbon-containing sediments for isolation of sulfonamides and triazines with recoveries ranging from 63% to 99%. Further cleanup (e.g., on Carbograph cartridges) or concentration (SPME) may sometimes be necessary.

**Supported liquid membranes (SLMs) or semipermeable membrane devices (SPMDs)** SLMs are passive *in situ* partitioning systems monitoring dissolved organic contaminants (in air/water/sediments). A porous polymeric

membrane (polyethylene or polytetrafluoroethylene, usually) is impregnated with an organic solvent, forming a barrier between two aqueous phases. The target analyte is extracted from the donor phase into the hydrophobic membrane and then back extracted into a second solution, the acceptor. The acceptor choice should be made according to the degree of lipophilicity of the target compounds. Di-*n*-hexyl ether, *n*-undecane, and triolein were successfully used as stagnant acceptors for 17 triazines, DDTs, DDDs, DDEs, diphenylethers, and chloronitrobenzenes. More polar herbicides, such as glyphosate, require cationic carriers incorporated to the membrane (Aliquat 336). The pH of the donor phase strongly influences extraction yields. Correlations between the log of the partition coefficients octanol-water ( $\log P$ ) characterizing target compounds and extraction yields have been made. Herbicide  $\log P$  values were determined by correlating their retention behavior in reverse-phase liquid chromatography (LC) with the water percentage in the mobile phase.

**Matrix solid-phase dispersion (MSPD)** MSPD is a sample preparation process dating back to 1989, realizing simultaneous disruption and extraction of solid or semisolid samples. The method is applied for the isolation of herbicides in tissues (animal or human origin), food, fruits, and vegetables. As an example, atrazine, cyanazine, metribuzin, and simazine were studied to determine their toxicity in aquatic media (including correlations with environmental temperatures and dissolved oxygen content) by monitoring their concentrations in catfish muscle and liver using MSPD as selective extraction step.

**Gum-phase extraction (GPE)** GPE is an application of the sorption phenomena on polymeric materials used during the sampling process at temperatures above their glass transition point ( $T_g$ ). In such conditions, polymeric materials no longer behave as pure solids but enter a gum-like or even liquid-like state with properties similar to those of organic solvents (considering diffusion and distribution constants). The commonly used sorbent is PDMS. Open tubular traps are more commonly coated in 1–3 m lengths of fused silica columns with 0.3–0.5 mm inner diameters and 10–15  $\mu\text{m}$  film thickness. Air samples should be sucked through the coated tubing. Trapped analytes are thermally desorbed into the gas chromatographic column. Extra column cryofocusing may be necessary. Stir bar sorptive extraction is based on the same principle but the polymer covers the external surface of a magnetic bar stirrer. The rod is inserted within the liquid sample and stirred for a defined period of time. The same effect is obtained if PDMS gum is packed into a cartridge and the liquid

sample is pushed through using LC pumps. Analytes are thermally desorbed directly in the gas chromatographic column or back extracted into an appropriate solvent, with subsequent solvent removal for concentration, redissolving, and injection to an LC column. Good recoveries were obtained for triazines analyzed in water samples when isolation was made as stated previously ( $\sim 75\%$  for simazine, atrazine, propazine, and sebuthylazine,  $\sim 80\%$  for terbutryn and prometryn, and  $\sim 110\%$  for terbuthylazine). Cyanazine, metribuzin, desisopropyl-atrazine, and desethylatrazine were poorly recovered ( $< 7\%$ ). Gas chromatography–mass spectrometry (GC–MS) was used for separation and detection.

**Size exclusion chromatography (SEC)** SEC is generally required as an isolation procedure for herbicides in fat matrices. High molecular mass compounds (e.g., triglycerides, sterols) are excluded from the stationary phase material, while the light fraction is eluted later and is collected for subsequent clean-up, separation, or analysis. A practical example is given by the determination of thiofensulfuron methyl and tribenuron methyl in cottonseeds and cotton gin trash. Restricted access (RA) or shielded materials combine the size exclusion principles with reverse-phase interactions and are also successfully used during sample preparation processes. Basically, RA materials have calibrated pores with strongly hydrophobic inner surfaces while the external particle surface is hydrophilic. Apolar analytes with low molecular masses are retained inside the pores while the medium to polar large molecule fraction is excluded. Applications are focused on biological samples (for protein exclusion and for high-speed immunoassays) (the detection principle is based on the chromatographic separation of the immunocomplex that was formed and the free remaining antigen). Immunoassays based on fluorescence detection using RA materials exist for atrazine and 2,4-D.

**Derivatization** Derivatization represents a chemical transformation induced to the target analyte in order to enhance its: (1) selective isolation; (2) chromatographic separation; and (3) sensitive detection. Derivatization is applied to nonvolatile herbicides for making gas chromatographic separations possible. Ampropylfos, glyphosate, glufosinate, and bialafos are reacted with trifluoroacetic anhydride (TFA) in the presence of trifluoroethanol. Phosphoro herbicides containing amino groups are esterified and acetylated simultaneously using acetic acid and trimethylacetate. Bis-trimethylsilyl trifluoroacetamide is often used for reacting hydroxyl or carboxyl active functions. The carboxylic group present in related

phenoxyacetic herbicides can be esterified at the same time or after their extraction. Chlorophenoxy-acidic herbicides may also be derivatized with pentafluorobenzoyl bromide in the presence of 18-crown-6 ether. Urea herbicides are derivatized with heptafluorobutyric anhydride (HPB) in toluene with pyridine addition, for sensitive electron capture detection (ECD). Under such conditions, difluorobenzuron is the only herbicide which decomposes. TFA or pentafluoropropionic anhydride is most reactive and forms more volatile compounds, but the increase in the ECD response is lower to HPB derivatives. 2,4-D, MCPA, 2,4,5-T, MCPB, and CCPB are derivatized through ion pairing prior to isolation using 1-cyano(2-trimethylammonium) ethylbenz(f)isoindole. Chlorophenoxy acids are derivatized for fluorescent detection in LC with 9-anthryldiazomethane. Sulfonyl urea, glibenclamide, and chlorpropamide are ultraviolet (UV) labeled with 2,4 dinitrofluorobenzene while uracils require 4-bromomethyl-6,7-dimethoxycoumarin.

## Separation Methods

### Thin Layer Chromatography

Phenoxyacetic herbicides are generally separated on Silicagel 60, Silicagel G/CaSO<sub>4</sub>, CaSO<sub>4</sub>, or Al<sub>2</sub>O<sub>3</sub>/CaSO<sub>4</sub>. Triazines are separated on silica plates. Preferred solvents for elution are acetone, benzene, carbon tetrachloride, chloroform, ethyl acetate, dioxane, and propanol. For urea herbicides, reversed phase C-18 plates were used for separation. Ion pair-based separation mechanisms are achieved on paraffin or methyl silicone-impregnated silica, using cetrimide or alkylammonium bromide as counterion. Eluents are based mainly on acetone and propanol mixtures. For increasing selectivity, sequential modes or bidimensional techniques are often used. Overpressure high performance thin layer chromatography (TLC) methods, driven at flow rates of 0.7–1 ml min<sup>-1</sup> and pressures of 1–2 MPa also increase separation power and the quality of the resulting plates. Identification is realized with acid–base indicators (e.g., bromophenol blue) for acidic herbicides, with chloroplasts homogenate for triazines, and ninhydrin for herbicides containing primary amino groups. Fluorimetric detection is also used. Densitometric UV detection made in the reflectance mode increases sensitivity and accuracy.

### Gas chromatography

GC is a powerful technique for herbicide separation. Due to the reactive organic functions contained by

the molecules of most herbicides, precolumn derivatization processes are often required.

**Injectors** Hot splitless injection (HSI) should be considered a rugged technique suitable for most herbicides. Flash vaporization is carried out at ~220°C for most analytes. Some phenyl ureas, carbamates, and organophosphorus compounds are susceptible to thermal degradation with HSI. On-column injection or programmed temperature vaporization (PTV) are offering powerful alternatives. Silanized glass wool inserts also favor decomposition of labile compounds. Some applications of large volume injection on PTV are also cited in the literature for phenoxyacetic, trichlorophenoxy acetic, and phenoxypropionic herbicides. Electronic pressure control with pulse programming reduces decomposition of carbamates on injection.

**Columns** Of the GC methods for herbicides reported in literature, more than 90% use capillary columns (25–30 m length, 0.25–0.32 mm inner diameter, and 0.15–0.30 µm film thickness). Medium polarity stationary phases are widely used (SE 52, 54, OV17, DB 5, DB7, or equivalent). Triazines and some phenyl ureas are separated also on apolar PDMSs (OV 1 or equivalent). Organophosphorus herbicides and chlorotriazines are separated with increased selectivity on SPB-35 or polyethylene glycols (Carbowax 20 M, Supelcowax RSL 300, or equivalent).

**Temperature programming** The temperature gradient is the key for tuning selectivity in GC. Starting program temperatures for triazines and phenyl ureas are lower (40–60°C) while higher values are used for phenoxy-carboxylic esters (80–85°C) and organophosphorus derivatives (100°C). Temperature gradients of 15–30°C min<sup>-1</sup> are generally used for less complex samples, up to 260–290°C, and a single ramp. Two different steps are required for complex mixtures or crowded matrices (first gradient range in the interval 10–25°C min<sup>-1</sup>, the second one between 3°C and 6°C min<sup>-1</sup>).

**Detection systems** Halogen-containing herbicides are detected at the picogram level with the ECD (<sup>63</sup>Ni). Low limits are also obtained in some cases with selective nitrogen–phosphorus detector (NPD) or electrolytic conductivity (Hall) detector (ELCD) detection (1 ng). Mass spectrometric detection is widely used due to its universal character as well as for its intrinsic sensitivity and selectivity. Both EI and CI (using methane or isobutane as reagent gases) are used for ionization. Specific ions monitored in the

**Table 3** Specific ions of some herbicides usually monitored in mass spectra

#	Name	Derivative	<i>m/e</i> signals (in the decreasing order of their relative abundance)

<sup>a</sup>Perfluorobutyl ester.

mass spectra for some of the herbicides or herbicide derivatives separated in GC are given in **Table 3**.

### Liquid Chromatography

LC still represents the most extensively used separation technique for herbicides.

**Stationary phases** Octadecyl-modified silica gel (ODS) either in monomeric or polymeric forms, of irregular or spherical shapes, with different end capping levels, is widely used for selective herbicide separation, according to the reversed phase mechanism (RP). Although the classical analytical column dimensions (25 cm length, 4.6 mm inner diameter) are still preferred, a lot of applications deal with the use of narrow bore (25 cm length, 1–2.1 mm inner diameters) or microbore packed (at least 30 cm length, 0.25 mm inner diameter) columns. The monolithic ODS columns introduced recently on the market are offering the advantages of higher elution speeds due to their increased porosity. Only few separations on cyano-modified silica gel were reported for triazines, using the normal phase (NP) separation mechanism. More often, chiral separations (for aryloxypropionic acids, for example) require optically active stationary phases and NP separation mechanisms. Capillary electrically driven chromatography (CEC) seems to represent a powerful alternative to LC. Octadecyldimethyl(3-trimethoxysilylpropyl)ammonium silica is

a stationary phase specially designed for CEC application on herbicide separation. The quaternary amine function generates the anodic electroosmotic flow while octadecyl functions are responsible for solute retention under a RP mechanism.

**Mobile phases** For RP-LC, mixtures of an aqueous component and organic solvents are invariably used. The aqueous component is eventually buffered (e.g., phosphate buffers 1–10 mmol l<sup>-1</sup> for triazines and phenylureas) or acid additivated (e.g., 0.1% phosphoric acid for chlorophenoxy acidic herbicides or 0.1–0.4% for phenoxyacetic herbicides). The organic solvents are mainly methanol, acetonitrile, or their mixtures. For NP-LC, hexane, dichloromethane, ethanol, and *iso*-propanol are frequently used.

**Detection systems** UV detection (including diode array detection, DAD, for spectral confirmation) is extensively used with LC. Triazines are detected at 220, 222, or 230 nm, phenoxyacidic herbicides at 240 nm, chlorophenoxyacidic herbicides at 220, 230, or 280 nm, carbamates at 245 nm, and substituted anilides at 220 nm. The higher value of the analytical wavelength, the poorer is the resulting detection limit and the less is the matrix interference. Fluorescence detection allows higher sensitivity (at least one order of magnitude) compared to UV, but also requires pre- or postcolumn derivatization (fluorescent labeling). Chlorophenoxy herbicides react with

9-anthryldiazomethane to generate fluorescent derivatives (ex. 365 nm, em. 412 nm), phenoxyacidic herbicides are derivatized with monodansyl cadaverine (ex. 366 nm, em. 450 nm), primary amino groups-containing herbicides yield products (ex. 230 or 340 nm, em. 420 or 455 nm) with *o*-phthalaldehyde and 2-mercaptoethanol. Some dinitroaniline derivatives undergo photoreduction in the presence of anthraquinone-2,6-disulfate to yield fluorescent products while benfluralin, trifluralin, isopropalin, and oryzalin are UV decomposed to active fluorescent degradation products. Electrochemical detection (including electrochemical array detection) can be considered as a sensitive alternative although it lacks robustness. MS undoubtedly offers a solution for a sensitive and selective detection. Mild ionization techniques such as electrospray interface (ESI) and atmospheric pressure chemical ionization (APCI) are rapidly covering a large selection of applications. Their flexibility and the fast interchangeability characteristics are strongly reducing restrictions on LC conditions in terms of flow rates, mobile phase

additives, diversity of analytes, etc. As a basic rule, polar compounds are better ionized with ESI while apolar ones with APCI. A few applications are reviewed in Table 4. The major drawback affecting LC/MS coupling is related to reduced possibilities of generating library searchable mass spectra. This inconvenience is overwhelmed by the recent creation of ESI–CID libraries for sulfonyl ureas (reproducibility of the resulting spectra is controlled over the collisional induced dissociation (CID) process realized in the electro spray transport region).

### Supercritical Fluid Chromatography

Some reports exist about separation of herbicides using capillary columns C-SFC (e.g., triazoles on a cross-linked CN with supercritical CO<sub>2</sub>/methanol mobile phase and UV detection). Owing to problems related to injection reproducibility and the overall method robustness, C-SFC is now obsolete. Interesting applications were obtained on packed columns (P-SFC).

**Table 4** Applications of mass spectrometric detection of herbicides in LC techniques

#	Analytes (class of compounds or compound)	Technique	Interface/ionization	Detection limits	Matrix
1	Triazines	LC/MS	APCI (+/-)	50 ng ml <sup>-1</sup>	Food
2	Sulfonylureas, diphenyl ethers, sulfonanilides	LC/MS/MS	TISP (+) (MRM)	10 ng ml <sup>-1</sup>	Soil
3	Benzoylureas	LC/MS	ESI (+/-); APCI (+/-)	10 ng ml <sup>-1</sup>	Ground water
4	Imidazolinones	LC/MS	ISP (+/-); APCI (+/-)	ng ml <sup>-1</sup> level	Tissues
5	Triazines	UHPLC/MS (TOF)	ESI (+/-)	ng ml <sup>-1</sup> level	Water
6	Alachlor	LC/MS	PBI (+ Cl; + EI)	ng ml <sup>-1</sup> level	Environmental water
7	Paraquat, diquat	LC/MS	ESI (+)	100 ng ml <sup>-1</sup>	Water
8	Sulfonylureas	LC/MS	ESI (+)	2–10 ng ml <sup>-1</sup>	Serum
9	Carbamates	LC/MS with buffer suppression	ESI (+)	ng ml <sup>-1</sup> level	Water
10	Imidazolinones, diphenyl ethers, sulfonylureas, aryloxyphenoxypropionic acids, triazolopyrimidines, sulfonanilides	LC/MS/MS	TISP (+) (MRM)	ng ml <sup>-1</sup> level	Environmental water
11	Diphenyl ethers	LC/MS/MS	TISP (+) v (SRM)	ng ml <sup>-1</sup> level	Environmental water
12	5-Trifluoromethylpyridone and metabolites	LC/MS	ESI	ng ml <sup>-1</sup> level	Hydroponically cultivated maize plants
13	Phenylureas	LC/LC/MS	APCI (+)	50 pg ml <sup>-1</sup>	Environmental water
14	Triazines, amides, phenylureas, triazoles, triazinones, benzimidazoles, phenoxyalkanoic herbicides	LC/MS and LC/MS/MS	ESI (-) for acidic compounds APCI (+)	20–100 pg ml <sup>-1</sup> 2–6 pg ml <sup>-1</sup>	Environmental water
15	Chlormequat	LC/MS/MS	ESI	7 ng ml <sup>-1</sup>	Fruits
16	Sulfonylureas, imidazolinones, sulfonamides	LC/MS	ESI (+)	10 pg ml <sup>-1</sup>	Water

TISP, turbo ion spray; MRM, multiple reaction monitoring; UHPLC, ultra-high-pressure liquid chromatography; TOF, time-of-flight mass analyzer; ISP, ion spray; SRM, selected reaction monitoring; ESI, electrospray interface; APCI, Atmospheric pressure chemical ionization.

**Columns** Pure silica, diol, or nitrile modified silica as well as ODS materials are used in P-SFC for herbicide separation. It is to be noted that in SFC all the cited phases behave as normal phases. This means that the stationary phase is always more polar than the mobile phase and, accordingly, the solutes are separated in order of increasing polarity. Reproducibility of retention data is very good, contrarily to NP-LC. Serially coupling two or more of the same type of columns will result in a fair increase of the efficiency while serially coupling of different columns can be a key in controlling selectivity.

**Mobile phases** SF-CO<sub>2</sub>/methanol mixtures are more often used in P-SFC. Gradient elution is offering a gain in terms of selectivity. Usually, methanol mobile phase content starts at 5% and increases up to 20% with 1–3% min<sup>-1</sup>. Flow rates are placed in the 2–3 ml min<sup>-1</sup> interval.

**Other conditions** Temperatures ~50°C are used in P-SFC for separation of herbicides, making this technique valuable for thermally labile compounds. Pressure programming is often used, in order to control the chromatographic run time. Generally, pressure gradients starting from 100 bar at 30 bar min<sup>-1</sup> up to 300 bar allows baseline separation of 8–12 compounds within 20 min. The high desorbing power of SF-CO<sub>2</sub> makes the online coupling of SPE and P-SFC very attractive. Limits in the low ng ml<sup>-1</sup> range are attainable when desorption takes place from the SPE cartridge directly to the P-SFC column. The cartridge drying period after sample loading seems to play a key role in the success of the online coupling.

**Detection** For P-SFC, UV detection (including DAD for spectral confirmation) is mainly used. Short wavelength detection (210 nm) generally increases sensitivity. Good results were obtained for separation of phenyl ureas and carbamates. The use of the APCI interfaces with practically no modifications compared to commercially available LC models increases the potential of the P-SFC technique. Triazines, carbamates, and sulfonyl ureas were separated in P-SFC and detected using APCI-MS. The APCI mass spectra mainly consist of the protonated molecular ion at low cone voltages. Increasing the CID voltage will induce greater fragmentation.

#### Micellar Electrokinetic Chromatography

Micellar electrokinetic chromatography (MEKC) applications are related to phenyl ureas, their corresponding metabolites, and methyl carbamates. Sodium dodecyl sulfate (SDS) and cetyltrimethylammonium

chloride are the commonly used surfactants. Reversed migration (RM)-MEKC using SDS and  $\gamma$ -cyclodextrin was also used for phenyl ureas. Stacking phenomena with RM micelles is often used as additional sample cleanup prior to separation. Addition of 10–20% organic solvent to the migrating media is controlling eventually arising solubility related problems. UV, fluorescence, or photochemical induced fluorescence is used for detection. Z-shaped flow cells in UV detection drastically increase sensitivity.

#### Capillary Zone Electrophoresis

Phenoxy acid herbicides, sulfonyl ureas, quaternary ammonium derivatives (quats), and aryloxy propanoic acids are the main classes of compounds subjected to capillary zone electrophoresis (CZE). Triazines are also separated using nonaqueous CZE, while low pK<sub>a</sub> characterized chlorotriazines require an ion-pair-like solubilization using cationic surfactants (tetradecylammonium bromide, dodecyltrimethylammonium bromide). Chiral selectors are added in CZE for obtaining enantioselectivity. Chiral selectors used for herbicide enantiomeric discrimination are vancomycin,  $\gamma$ -cyclodextrin, ethyl carbonate  $\beta$ -cyclodextrin, cyclohexyl-alkyl- $\beta$ -D-maltoside, sulpropyl ether  $\alpha$ -cyclodextrin, and hexakis(2,3-di-O-methyl)- $\alpha$ -cyclodextrin.

### Analytical Methods

#### Qualitative Reactions

These qualitative methods of analysis are dependent upon characteristic chemical reactions of herbicides to produce colored compounds or metal complexes (see Table 5). The detection limit of these spot tests ranges from micrograms to milligrams.

#### Titrimetric Methods

Acid–base titrations with perchloric or hydrochloric acid characterize the herbicides containing basic moieties such as aliphatic or aromatic primary or secondary amines (atratone, ametryn, prometryn, prometone). Titrations, generally with standard sodium hydroxide solutions, are used for herbicides containing acidic moieties such as carboxyl or phenolic hydroxyl groups (3-amino-*s*-triazole, sesone, maleic hydrazide). Redox titrimetry is specific for herbicides containing a reducing site such as phosphite residues (oxidizable to phosphate) or phenolic structures (oxidizable to quinones). As an example, falone is determined by titration with alcoholic iodine solution. Precipitation titrimetry could also be used for all herbicides for which the organically bound chlorine can be converted to chloride

**Table 5** Color reactions for qualitative identification of herbicides

<i>Herbicide class</i>	<i>Compound</i>	<i>Reagent</i>	<i>Color</i>
Organic acids	TCA	Pyridine + NaOH	Red-violet, after heating
	2,4-D	Formaldehyde + H <sub>2</sub> SO <sub>4</sub>	Pink, after heating
	Endothal	FeCl <sub>3</sub>	Violet-purple
Amides	CDAA	CS <sub>2</sub> , Cu <sup>2+</sup>	Yellow
	Dicryl	NaOH, NaNO <sub>2</sub> + HCl, N-1-naphthylethylenediamine	Purple
Arylcarbamates	Propham	NaOH, NaClO	Blue
Aminotriazoles	Amitrole	NaOH, sodium nitroprusside (Na <sub>2</sub> [Fe(CN) <sub>5</sub> (NO)] · 2H <sub>2</sub> O)	Green

(e.g., sample refluxing with sodium in ethanol). Silver nitrate is used as titrant. Radox and vegadex are quantified in such a manner. Titrimetric methods are exclusively used as quantitation tools for individual compounds in herbicide formulations. The main advantages of chemical methods are their simplicity and low analysis costs. However, selectivity and sensitivity are poor.

### Spectrometric Methods

Spectrometric methods are commonly used for structural characterization. A linear relationship between absorbance and concentration of the chemical species makes them also suitable for quantification of small concentrations of analyte.

**Ultraviolet-visible spectrometry** UV activity is related to the existence in the herbicide structure of aromatic rings and unsaturated heterocycles. For accurate quantification of herbicides, elimination of matrix effects is an essential process. In some cases, hydrolysis is used in order to displace the analyte signal to a spectral region unaffected by matrix interferences. Table 6 shows the absorption maxima and molar absorptivities of some widely used herbicides. There are only a few herbicides having spectral activity in the visible region of the spectrum. The intensities of the bands are low, and consequently are unsuitable for trace analysis. Sensitive detection can be achieved, however, by derivatization. For increasing selectivity, derivative UV spectrometric methods can be applied for more complex mixtures (e.g., zero-crossing technique). Simazine, propazine, hexazinone, bromacil, and metoxuron were analyzed accordingly. On using derivative spectrometry, relative standard deviations (RSDs) for the determined values are normally below 4% and recoveries ranged in the interval 95–110%.

**Infrared spectrometry** This technique has powerful applications in the structure confirmation of

**Table 6** UV absorption data for some herbicides

<i>Compound</i>	<i>Absorption maximum (nm)</i>	<i>Molar absorptivity (l cm<sup>-1</sup> mol<sup>-1</sup>)</i>
2,3,6-TBA	206	35 000
	277	320
	286	270

	230	7 500
	283	1 900
	291	1 600
2,4,5-T	207	61 000
	298	1 200

herbicides. It can be used as a detection system in GC separations, if the functioning principle of the detector is Fourier transform based. The existence of a great number of spectral bands allows the analytical scientist to choose one that is less affected by matrix interferences. Sensitivity of IR spectrometry for quantitative methods is usually limited to microgram amounts. For GC-FTIR detection, multiple reflection detection cells or the matrix isolation setup will increase sensitivity.

**Nuclear magnetic resonance (NMR) spectrometry** NMR is mainly used for structural studies. Its intrinsic lack of sensitivity is compensated by the deep structural information provided (including conformation, chirality, inclusion phenomena, etc.). Full characterization of the major metabolites of 5-trifluoro-methylpyridone has been achieved by means of NMR detection in LC. The combination of NMR and MS data allowed identification of the N-glucoside and O-malonylglucoside conjugates of the parent pyridone. NMR (<sup>31</sup>P) was also used for the determination of the stability constants of the

complexes between some transition cations and nitriolo-tris(methylenephosphonato) herbicides.

**Fluorimetry and chemiluminometry** Only a few herbicides are fluorescent (e.g., indole 3-acetic acid, 1-naphthylacetic acid, and 2-naphthoxyacetic acid). As a general rule, the presence of the chlorine atoms in the molecule quenches fluorescence. Nonfluorescent herbicides are transformed to fluorescent ones by derivatization. Quantification of herbicides is also possible by measuring the radiative emission generated during a specific chemiluminescent reaction of the analyte. Phenolic herbicides are easily determined in soil samples by the peroxyoxalate chemiluminescent reaction. The first step of the process is the oxalate-herbicide ester formation in anhydrous media, using oxalyl chloride as reagent. The ester is then dissolved in tetrahydrofuran containing 9,10-diphenylanthracene. Chemiluminescence is generated by direct addition into the system of a concentrated hydrogen peroxide solution. Determination is made 1 and 3 s after peroxide addition. Bromofenoxim, bromoxynil, and *p*-cyanophenol were determined in such a way at the  $1 \text{ pmol l}^{-1}$  level.

**Mass spectrometry** Some herbicides can be determined directly in unextracted solid samples by thermolysis-APCI-MS/MS (a single MS process is strongly affected by matrix interferences). The condition for satisfactory results is the thermal stability of the analytes under the analytical conditions, yielding mass spectra with intense molecular ions at higher *m/e* values. Determination of atrazine, ametryn, and propazine fall in the  $10\text{--}100 \text{ pg ml}^{-1}$  range when using MS/MS and multiple reaction monitoring (MRM). Aerosol mass spectrometry with laser-desorption/ionization has also been investigated as a possible tool for real-time monitoring of the presence of herbicides on the surface of airborne soil particles. This technique applied for paraquat produces only singly charged ions, the most abundant species being  $\text{M}^+$ ,  $[\text{M} - \text{H}]^+$ , and  $[\text{M} - \text{CH}_3]^+$ .

## Electrometric Methods

**Amperometric biosensors** Biosensors are devices coupling biological components (providing high selectivity and/or sensitivity) to a physicochemical transducer recording and amplifying the signal. A typical amperometric microcell contains a working and counter electrodes of platinum and an SCE reference electrode. A neutral buffer containing thylakoid membranes isolated from plant leaves immobilized on albumin, introduced in the amperometric cell, under irradiation of a halogen lamp at

$109 \text{ W cm}^{-2}$ , produces a photocurrent. Triazine herbicides induce a decrease of the photocurrent proportional to the concentration of the sensed compound. Class-selective amperometric microcells (e.g., triazine and phenylurea type selective against phenolic herbicides) were developed using photosynthesis complexes (PSII) isolated from the thermophilic cyanobacteria *Synechococcus elongatus*. The biosensing element is immobilized on the surface of a screen printed sensor composed of a graphite working electrode and an Ag/AgCl reference electrode deposited on a polymeric substrate. The microcell is illuminated. The principle of detection is based on the fact that herbicides are selectively blocking PSII electron transport activity in a concentration-dependent manner. Changes of the activity were registered as the rate of the photoreduction of an artificial electron acceptor. Detection limits fall in the  $10^{-9} \text{ mol l}^{-1}$  range.

Pseudohomogenous amperometric displacement immunosensors have also been developed. The displacement assay is performed on a disposable screen printed carbon electrode and takes advantages of the cross-reactivity of some monoclonal antibodies. As an example, the monoclonal anti-2,4-D antibody exhibits a relative cross-reactivity toward immobilized MCPA. In the presence of the target analyte (2,4-D) a displacement effect is observed. Consequently, the peroxidase label of the remaining anti-2,4-D antibodies is detected at the carbon electrode, when adding hydrogen peroxide and potassium iodide as redox mediator, at 0 V versus Ag/AgCl.

**Polarographic techniques** Polarographic processes can be generated by reduction or oxidation reactions involving electrochemically active functional groups (e.g., nitro, carbonyl, carboxyl, carboimide groups). The polarographic signals of different herbicides present together in the sample may exhibit great overlap (e.g., atrazine against simazine, terbutryn against prometryn). For this reason, different multi-component approaches such as partial least squares and artificial neural networks could be used for enhancing resolution. Square wave and differential pulse voltammetric methods are proposed for the determination of paraquat and diquat, based on their oxidation peak at the glassy carbon electrode, following their degradation in strongly alkaline media. Differential pulse polarographic determination of aziprotryne and desmetryn based on their reduction in biphasic media (as oil in water emulsions) was also reported. Sulfonyl ureas are also subject to differential pulse polarography, in homogenous aqueous methanolic potassium chloride media, acidified with perchloric acid. Cyclic, differential pulse, and square wave voltammetry were also applied for

determination of molinate, bensulfuron-methyl, mefenacet, and thiobencarb used to treat rice crops. Attention should be focused on the adsorption and consequent poisoning of the electrode surface by the products of the electrochemical reaction. Undoubtedly, polarographic techniques are the most sensitive electrometric methods for herbicide determination, but are not selective enough for most of environmental samples.

### Enzyme Methods

The enzymatic assay of herbicides is methodologically based on their common pharmacological property to inhibit the activity of a group of enzymes involved in the hydrolysis of choline esters. When an enzyme activity is measured under controlled conditions, the degree of inhibition induced by the sample is a measure of the quantity of the target herbicide. The enzymatic analytical process involves competitive interactions between the enzyme and the substrate, on the one hand, and between the enzyme and the target analyte, on the other.

### Immunoassay

Chemical measurements based on immune reactions have proved to be versatile tools for herbicide analysis. Crude extracts of plant tissues, soil, water, and biological specimens such as blood, urine, or bovine rumen fluids can be assayed for herbicide contamination using enzyme multiplied immunoassay technique or enzyme-linked immunosorbent assay (ELISA). Both techniques are designed to measure microgram or sub-microgram levels of herbicides in test samples, combining the convenience, speed, and reproducibility of the enzyme measurement with the selectivity and the sensitivity of immunoassays. Immunoassays can also be developed for the herbicide metabolites. As an example, hydroxypropazine, hydroxyatrazine, and hydroxysimazine assays are based on a covalent immobilization of antigen in combination with an enzyme-labeled anti-hydroxy-s-triazine monoclonal antibody. Sometimes, even such selective systems do not differentiate the parent structure from its metabolites. The competitive indirect ELISA method developed for quantitation of glyphosate using glyphosate polyclonal antisera did not cross-react with a large number of herbicides, but did cross-react with the metabolite aminomethylphosphonic acid and a structurally related herbicide glyphosine. Contrarily, polyclonal antibodies developed in rabbits against the haptenic analog *N*-(2,6-dinitro-4-trifluoromethylphenyl)-*N*-n-propyl-6-amino-hexanoic acid exhibit increased selectivity for the herbicide trifluralin, even in complex matrices such

as vegetable juices. Some interference from ethalfluralin and benfluralin are observed, while isopropalin and pendimethalin did not show cross-reactivity. Because herbicides are often extracted from different matrices in organic solvents, a lot of work was directed toward the ability of immunosystems to act in mixed water/organic or even pure organic media. Finally, the existence of affinity interactions in pure organic solvent has been proved (e.g., 2,4-D and DCB modified with a polystyrene moiety functioning as a mass label interact in pure toluene, triazine, and phenylureas could be detected in pure ethanol and hexane using covalent immobilization of the respective monoclonal antibodies K4E7 and B76-BF5).

### Biological Assay

Biological assay is based on a measurable growth response from a test organism, as a result of the biological action of any compound. In many instances, this growth response will be an inhibition of elongation or a curvature of an organ such as a stem. The validity of biological assay procedures is based on two assumptions: (1) the plant response increases with the dose of the herbicide; and (2) within the limits of sample variation, these responses are reproducible when the plant material and the environmental conditions are the same. Under controlled conditions these techniques are very sensitive and accurate for solutions of pure chemicals. Their use for determination of herbicides in a matrix of plants or soils is seriously affected by errors. Biological assay is suitable for the phenoxyacetic acids (2,4-D, MCPA, 2,4,5-T) and triazinic herbicides.

### Introduction

Narcotic analgesic agents, including heroin, morphine, codeine, hydrocodone, oxycodone, and methadone, account for a significant number of drug-related illnesses, injuries, and deaths. According to the 2002 data collected by the US Department of Health and Human Services Drug Abuse Warning Network (DAWN), heroin was the third most frequently mentioned illicit drug in emergency-room episodes within the US. Current trends suggest an increase in heroin use among younger populations. In addition, the preferred route of administration seems to be changing from injecting to smoking or snorting. This change may be due to an increased awareness of HIV and other infectious diseases, as well as the increase in purity of heroin.

Heroin (3,6-O-diacetylmorphine, diamorphine) was first synthesized from morphine by an English chemist, CR Wright, in 1874, and was introduced commercially as a morphine-like analgesic by the Bayer Company of Germany in 1898. Heroin was initially used as a morphine and codeine substitute for the treatment of tuberculosis and other respiratory illnesses. However, it quickly became apparent that this drug was more toxic than morphine and exhibited equivalent abuse liability and tolerance-

producing properties. As a result, during the early 1900s, laws were enacted in many countries to reduce the demand for opiates. For example, legislation was passed in 1914 in the US to restrict the distribution of narcotics, but use in medical practice was still permitted. Several years later, federal law prohibited any use, including medical, of heroin. An epidemic of heroin use in the US occurred during the post-World War I period and more recently, during the early 1970s. Despite continuing attempts at restricting the supply and demand for heroin, illicit use continues unabated and is a major problem for most law-enforcement agencies. Since heroin has a substantial potential for abuse and has no currently accepted medical use in the US, it is presently classified as a Schedule I substance according to the US Code of Federal Regulations. In accordance with measures recommended by international organizations such as the World Health Organization, other nations classify heroin similarly in order to control availability, and if applicable, ensure that heroin is used exclusively for medical and scientific reasons. There are various United Nations (UN) agreements that address the use and misuse of opium alkaloids. The Single Convention on Narcotic Drugs of 1961 as amended by the 1972 Protocol, the Convention on Psychotropic Substances of 1971, and the United Nations Convention against Illicit Traffic in Narcotic Drugs and Psychotropic Substances of 1988 help to establish the guidelines for the international manufacture, distribution, and consumption of narcotic drugs. Many countries adhere to the policies set forth by these treaties and the International Narcotics

### Introduction

Narcotic analgesic agents, including heroin, morphine, codeine, hydrocodone, oxycodone, and methadone, account for a significant number of drug-related illnesses, injuries, and deaths. According to the 2002 data collected by the US Department of Health and Human Services Drug Abuse Warning Network (DAWN), heroin was the third most frequently mentioned illicit drug in emergency-room episodes within the US. Current trends suggest an increase in heroin use among younger populations. In addition, the preferred route of administration seems to be changing from injecting to smoking or snorting. This change may be due to an increased awareness of HIV and other infectious diseases, as well as the increase in purity of heroin.

Heroin (3,6-O-diacetylmorphine, diamorphine) was first synthesized from morphine by an English chemist, CR Wright, in 1874, and was introduced commercially as a morphine-like analgesic by the Bayer Company of Germany in 1898. Heroin was initially used as a morphine and codeine substitute for the treatment of tuberculosis and other respiratory illnesses. However, it quickly became apparent that this drug was more toxic than morphine and exhibited equivalent abuse liability and tolerance-

producing properties. As a result, during the early 1900s, laws were enacted in many countries to reduce the demand for opiates. For example, legislation was passed in 1914 in the US to restrict the distribution of narcotics, but use in medical practice was still permitted. Several years later, federal law prohibited any use, including medical, of heroin. An epidemic of heroin use in the US occurred during the post-World War I period and more recently, during the early 1970s. Despite continuing attempts at restricting the supply and demand for heroin, illicit use continues unabated and is a major problem for most law-enforcement agencies. Since heroin has a substantial potential for abuse and has no currently accepted medical use in the US, it is presently classified as a Schedule I substance according to the US Code of Federal Regulations. In accordance with measures recommended by international organizations such as the World Health Organization, other nations classify heroin similarly in order to control availability, and if applicable, ensure that heroin is used exclusively for medical and scientific reasons. There are various United Nations (UN) agreements that address the use and misuse of opium alkaloids. The Single Convention on Narcotic Drugs of 1961 as amended by the 1972 Protocol, the Convention on Psychotropic Substances of 1971, and the United Nations Convention against Illicit Traffic in Narcotic Drugs and Psychotropic Substances of 1988 help to establish the guidelines for the international manufacture, distribution, and consumption of narcotic drugs. Many countries adhere to the policies set forth by these treaties and the International Narcotics

Control Board plays a role in monitoring adherence to these policies.

## Chemistry

Heroin is produced by the direct acetylation of morphine, an alkaloid obtained from the dried latex of incised unripe flower pods of the opium poppy *Papaver somniferum* L. Opium is cultivated in Southeast Asia, Turkey, Pakistan, Afghanistan, India, Iran, Nigeria, and Mexico. The only chemicals needed to produce heroin clandestinely from opium are calcium hydroxide, a pH modifier, and an acetylating agent. As shown in **Figure 1**, in the presence of excess acetic anhydride and heat, the 3- and 6-hydroxyl groups of morphine are acetylated, yielding heroin. After acetylation, the solution is usually neutralized with sodium carbonate and treated with concentrated hydrochloric acid in order to produce heroin hydrochloride. ‘Street-grade’ heroin is usually sold as the hydrochloride salt.

The predominant constituents of raw opium are alkaloids, fatty acids, sterols, alcohols, resins, sugars, and plant fragments. At least 30 alkaloids have been identified and have been classified into two categories, phenanthrenes and benzyloquinolines. The phenanthrene alkaloids include morphine, codeine, and thebaine, and the benzyloquinoline alkaloids consist of papaverine and noscapine. If not removed during preparation, many of these compounds will be present in heroin as minor contaminants.

The chemical and physical appearance of illicit heroin varies depending upon its origin and synthesis. Pure heroin is a fine white powder, whereas illicit heroin varies in appearance from white to dark brown. Crudely processed heroin, known as black tar, is dark brown to black. The quantity and purity of heroin produced during illicit manufacture is a function of the alkaloidal content of the raw opium, the procedures used to extract morphine, and the techniques used during acetylation and the purification processes. Prior to distribution, illicit heroin is usually mixed with bulk diluents such as quinine,

mannitol, dextrose, lactose, and baking soda. Paracetamol, lidocaine, and procaine are sometimes added to enhance the effect of heroin or to relieve pain during injection. The purity of street-grade heroin in the US varies greatly from 1% to 60%. If sold undiluted, the purity of black tar heroin may range as high as 40–80%. **Table 1** summarizes compounds often found in illicit heroin. Using various separation techniques and statistical methods, these compounds can be separated from the heroin and characterized in order to track the origin of the heroin sample.

The physicochemical effect of the addition of two acetyler functional groups to morphine is to decrease molecular polarity, and thus increase lipid solubility and membrane permeability. Heroin is a strong base with a  $\text{pK}_a$  of 7.6 at  $23^\circ\text{C}$  and readily hydrolyzes to 6-acetylmorphine under various conditions. Heroin is especially susceptible to base-catalyzed hydrolysis, but will also hydrolyze in the presence of protic solutions including alcoholic and

aqueous media. Free base heroin is soluble in chloroform, alcohol, and ether and is insoluble in water. Heroin hydrochloride is soluble in chloroform, alcohol, and water. Heroin is increasingly unstable as the temperature of the solution increases. As a result of its instability, aqueous pharmaceutical preparations of heroin must be prepared shortly before use in order to ensure potency. A summary of the physical and

chemical properties of heroin is shown in Table 2. Heroin is rapidly and extensively metabolized in the human body. The metabolic pathway of heroin is illustrated in Figure 2.

## Forensic Identification

Opiate materials submitted to forensic chemistry laboratories for identification are subjected to an analytical scheme that includes a combination of initial screening tests leading to presumptive positives and confirmatory testing with more specific methods. Illicit heroin reacts with most alkaloidal precipitation reagents including the Liebermann's, Mandelin's, and Marquis color tests. In the presence of heroin, these reagents produce black, blue-gray, and violet colors, respectively. Heroin reacts with platinum chloride and mercury(II) chloride reagents forming small golden yellow clustered needles and rosettes, respectively, which can be viewed microscopically. The color or microcrystalline formation produced by the reaction of heroin with these reagents is not necessarily specific to heroin since other opium alkaloids including morphine and codeine produce similar results. Furthermore, the formation of color may be affected by the reaction of strong acids present in the reagents with impurities, such as sugars, found in illicit heroin. The microcrystalline precipitation

procedures can be affected by impurities in heroin, producing irregular and/or imperfect crystals.

Opiates can be identified by thin-layer chromatography (TLC) with many different combinations of mobile-phase solvent systems and detection reagents. A solvent system prepared with ethyl acetate–methanol–ammonium hydroxide (85:10:5) is commonly used to resolve heroin, codeine, acetylcodeine, morphine, and acetylmorphine. After development, opiates can be visualized by spraying or dipping the chromatogram in Dragendorff, iodoplatinate, or Marquis reagent.

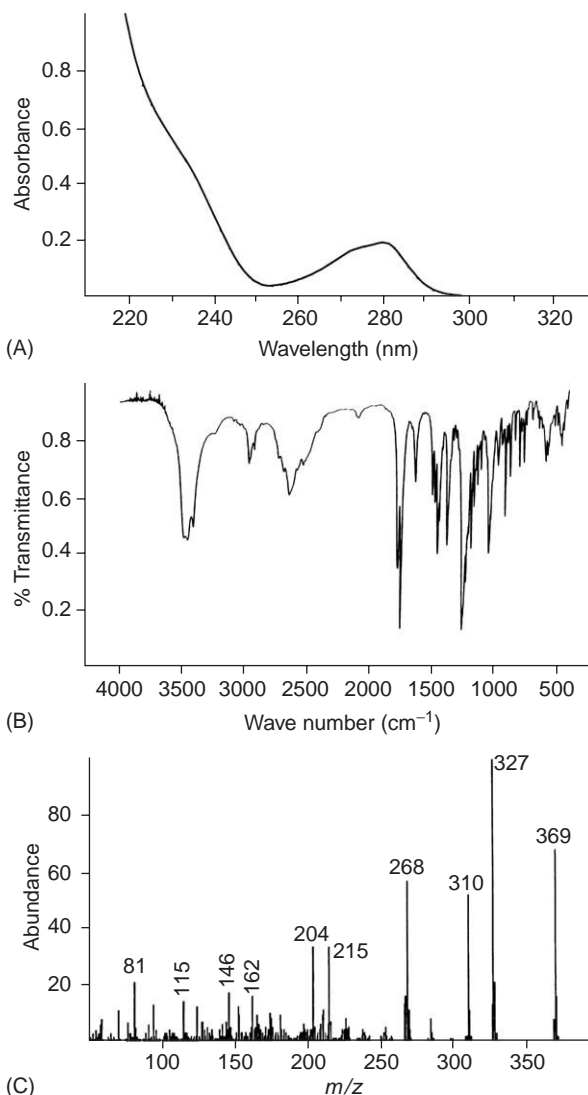

After screening tests have been completed, instrumental techniques such as ultraviolet (UV)–visible spectrophotometry, liquid chromatography (LC), and gas chromatography (GC) are used to confirm the presence of heroin. To analyze an unknown opiate by instrumental analysis, the sample is dissolved and extracted with a suitable solvent. The UV spectrum of pure heroin prepared in dilute acid is shown in Figure 3A. In dilute aqueous acid, the absorbance maximum is 279 nm.

Either LC with UV detection or GC with flame ionization detection can be used to identify and quantify heroin and related compounds. These techniques have been used extensively by many laboratories to assay heroin samples. A study of the chemical composition of illicit heroin samples also can reveal the geographical origin of the opiate material.

Infrared (IR) spectrophotometry and gas chromatography–mass spectrometry (GC–MS) are commonly utilized to confirm the presence of heroin. Both IR and MS of heroin are unique and are easily distinguishable from other related compounds, thus providing a high degree of confidence in the identification process. The Fourier transform (FT) IR and MS spectra of heroin are shown in Figures 3B and 3C. The major IR absorption peaks for heroin hydrochloride, prepared in potassium bromide, are 1753, 1732, 1365, and 1230  $\text{cm}^{-1}$ . The primary spectral features of heroin by electron-impact MS are ions at  $m/z$  369, 327, 310, and 268.

## Analysis of Biological Specimens

The analysis of heroin in biological specimens is difficult because heroin is rapidly metabolized *in vivo* and is subject to chemical and metabolic/enzymatic hydrolysis *in vitro*. In addition, the effective therapeutic dose of heroin is small owing to its high potency, and thus, biological fluid and tissue heroin concentrations are exceedingly low. Therefore, in order to quantify heroin accurately in tissues, adequate

**Figure 3** (A) UV spectrum of heroin in  $0.1 \text{ mol l}^{-1}$  sulfuric acid. (B) Fourier transform IR spectrum of heroin hydrochloride in potassium bromide. (C) Electron-impact mass spectrum of heroin.

precautions during specimen handling and extract preparation must be taken in order to stabilize heroin and 6-acetylmorphine. Heroin can be stabilized by rapid freezing of specimens following collection and by preventing *in vitro* hydrolysis by adding esterase inhibitors such as sodium fluoride.

Heroin or its metabolites have been identified in various biological matrices including: plasma, urine, and saliva collected from human subjects administered heroin; hair and sweat collected from heroin users; urine, vitreous humor, and cerebrospinal fluid collected from cadavers whose death was due to narcotic intoxication; and meconium collected from infants with prenatal exposure to heroin. Frequently, only morphine is assayed because of the instability of heroin and 6-acetylmorphine in blood, plasma, and

urine. Since most specimens do not contain intact heroin, biological specimens testing positive for morphine are usually presumed to have arisen as a result of heroin use. However, since codeine is also metabolized to morphine, it may be necessary to test for a specific metabolite of heroin, 6-acetylmorphine, to establish that heroin was used. In addition, studies have indicated that acetylcodeine, detected in urine and hair, is a potential marker for illicit heroin use.

## Extraction

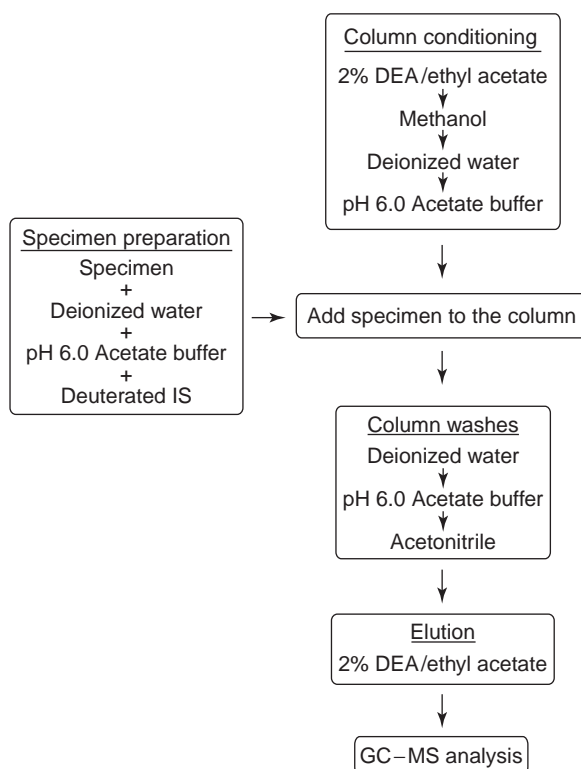

Heroin and its metabolites can be isolated from human and animal biological fluids and tissues by various procedures including liquid–liquid and solid-phase extraction techniques. In order to prevent overestimation of 6-acetylmorphine resulting from the hydrolysis of heroin, heroin and 6-acetylmorphine standard curves can be prepared and extracted separately. Final results must be corrected for the percentage conversion of heroin to 6-acetylmorphine.

Historically, heroin was first isolated by a procedure based upon alkaline extraction with 10% butanol in chloroform. 6-Acetylmorphine and morphine were separated from heroin by paper chromatography or countercurrent distribution. Countercurrent separation was accomplished with an eight-transfer system with ethylene dichloride and phosphate buffer.

The first practical method developed for the simultaneous determination of heroin and its metabolites utilized a complex multistep liquid–liquid extraction scheme. Under mild alkaline conditions, analytes from plasma are isolated with a mixture of toluene–butanol. The analytes are back-extracted into dilute sulfuric acid and the acid phase is washed with *n*-hexane. After adjusting the pH, the aqueous phase is extracted with toluene–butanol. Following separation and evaporation of the organic phase, the extract is reconstituted in methanol and analyzed by LC.

Heroin and metabolites have been isolated from the hair of heroin addicts with a single-step liquid–liquid extraction procedure. Under mild alkaline conditions, a mixture of toluene–heptane–isoamyl alcohol is added to the specimen and, after mixing, the organic phase is removed, evaporated, and derivatized with *N*-methyl-bis(trifluoroacetamide). The derivatized extract is subjected to GC–MS analysis.

Solid-phase extraction using co-polymeric bonded phases with hydrophobic and cation exchanged functionalities has also been used for the extraction of heroin and metabolites from biological fluids and tissues. Solid-phase extraction can yield clean extracts with efficient recovery of analytes. In

**Figure 4** Simplified solid-phase extraction scheme for heroin and metabolites. IS, internal standard; DEA, diethylamine; GC–MS, gas chromatography–mass spectrometry.

addition, since drug isolation and subsequent extraction are rapid, hydrolysis of heroin to 6-acetylmorphine can be reduced or eliminated. A simplified solid-phase extraction scheme is shown in Figure 4.

## Detection Techniques

### Immunoassay

Clinically, opiates are detected in biological specimens by a variety of commercial screening techniques including enzyme multiplied immunoassay, radioimmunoassay, and fluorescence polarization immunoassay. Opiate immunoassays are usually designed to detect morphine and morphine-3-glucuronide (conjugated morphine) as the target analytes and most are formulated to provide qualitative or semiquantitative results. Most opiate assays generally exhibit significant cross-reactivity with other opioid compounds such as codeine, hydromorphone, hydrocodone, and dihydrocodone; consequently, routine and forensic confirmatory analysis of presumptive positive specimens requires identification by a more specific technique such as GC–MS.

### Spectrophotometry, Paper Chromatography, and Thin-layer Chromatography

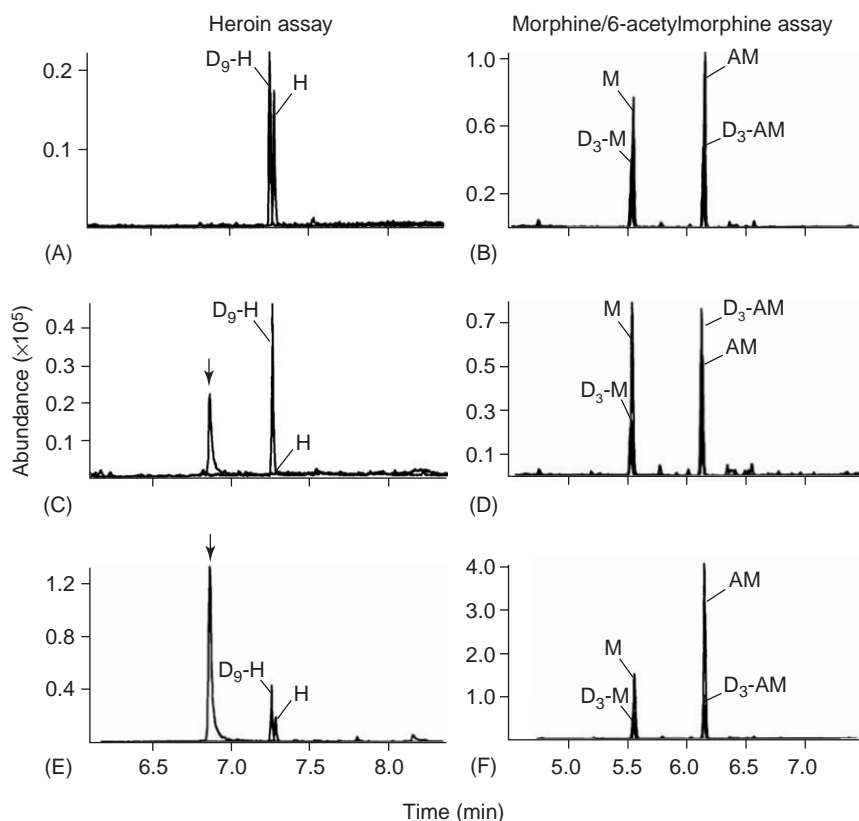

Early analytical methods developed to assay heroin and its metabolites in biological fluids and tissues utilized indicator-dye, paper chromatography (PC), and TLC techniques. Indicator-dye techniques, based upon the reaction of organic bases with colored organic acids such as methyl orange to form complexes soluble in organic solvents, were used to quantify heroin and metabolites. The colored complexes were subsequently measured by spectrophotometry.

Early studies of the disposition and metabolism of heroin in humans and animals were performed with PC and TLC. Heroin, 6-acetylmorphine, and morphine were separated by normal-phase and reversed-phase chromatographic systems. The analytes were visualized by spraying with iodoplatinate, Folin-Ciocalteu reagent, or Dragendorff's reagent.

### Liquid Chromatography

LC with either normal- or reversed-phase systems can be used to measure heroin and metabolites. In order to produce accurate measurements of heroin, liquid chromatographic systems must employ aqueous mobile phases of low hydrolytic activity (e.g., neutral pH and low alcohol content). Since reversed-phase chromatographic analysis of weak bases requires suppression of analyte ionization by increasing the pH of the mobile-phase, normal-phase chromatography is used for the analysis of heroin owing to heroin's instability at elevated pH.

For analysis of heroin metabolites, reversed-phase chromatography coupled with electrochemical detection is frequently used. Other methods used to improve sensitivity include oxidation to fluorescent pseudomorphine-like dimers using potassium hexacyanoferrate(III) and derivatization using a fluorescent chromophore such as dansyl chloride. Detection by MS or tandem MS after separation by LC is

**Figure 5** SIM recordings of standards and postmortem blood and urine specimens. Panels A and B illustrate 15 ng ml<sup>-1</sup> heroin standard and 50 ng ml<sup>-1</sup> 6-acetylmorphine and morphine standards, respectively. Panels C and E illustrate a postmortem blood specimen. Panels D and F illustrate a postmortem urine specimen diluted 1:10 with distilled water. Arrows in panels C and E denote presence of underivatized 6-acetylmorphine. Chromatograms were constructed with the following ions: heroin, *m/z* 327; d<sub>9</sub>-heroin, *m/z* 334; morphine, *m/z* 364; d<sub>3</sub>-morphine, *m/z* 367; 6-acetylmorphine, *m/z* 364; and d<sub>3</sub>-6-acetylmorphine, *m/z* 367. (Reproduced with permission from Goldberger BA, Cone EJ, Grant TM, *et al.* (1994) Disposition of heroin and its metabolites in heroin-related deaths. *Journal of Analytical Toxicology* 18: 22–28.)

becoming increasingly popular. Various ionization techniques like electrospray and atmospheric pressure ionspray are used for the MS detection of heroin, 6-acetylmorphine, morphine, morphine 3-glucuronide, and morphine-6-glucuronide.

### Gas Chromatography

Heroin is generally present in biological fluids and tissues at very low concentrations, whereas the metabolites 6-acetylmorphine and morphine may be present in much higher concentrations. Consequently, heroin metabolites are frequently measured by GC with flame ionization, nitrogen–phosphorus, electron-capture detection, or MS. Depending upon the chromatographic system, derivatization of 6-acetylmorphine and morphine to perfluorinated or silylated derivatives is performed to improve analyte volatility, aid chromatographic performance, and enhance detector response.

Because of its sensitivity and specificity, GC–MS is the most commonly used technique for forensic and clinical testing of heroin and metabolites. Analysis of heroin does not require derivatization; however, derivatization of morphine and 6-acetylmorphine to perfluorinated or silylated derivatives is necessary to improve chromatographic response. Coupled with solid-phase extraction, analysis of heroin by electron-impact mass spectrometry can produce accurate and precise measurement of heroin and metabolites. **Figure 5** panels A and B illustrate characteristic selected ion monitoring (SIM) recordings of extracts of a  $15 \text{ ng ml}^{-1}$  heroin standard and a  $50 \text{ ng ml}^{-1}$  6-acetylmorphine and morphine standard, respectively. Both standards had been prepared in a blood matrix. Panels C–F illustrate SIM tracings of postmortem blood and urine extracts. The arrow in panels C and E denotes the presence of underivatized 6-acetylmorphine.

## Antiquity and the Middle Ages

The use of the senses of taste, touch, sight, and smell are 'methods', as old as mankind itself, for examining and ascribing characteristics to various materials. They may thus be considered to be the oldest analytical techniques. In many fields, such as food and drink, they have stood the test of time, some of them are now elegantly called 'organoleptic tests'. However, throughout history there have been important materials that could not be characterized by the senses and other methods were sought.

Among the first materials to be tested by such methods were the precious metals, gold and silver. Testing of gold by cupellation or fire assay was mentioned by many ancient writers including Biblical Old Testament authors. The assay was carried out in essentially the same way as it is today: melting with lead, then elimination of the lead by oxidation and adsorption in the cupel, followed by weighing of the noble metal nugget (Figure 1). Balances were available to the ancients; for example, in Sumerian cities 5000–6000 years ago.

The earliest recorded attempt in England at regulating the standard for gold and silver wares was the order in 1288, passed by King Henry III. In 1300, the method of assay by touchstone was prescribed. The touchstone test was known in early times and described by Pliny, ~AD 60. Similar controls

were put in place in other nations, for example, King Charles Robert of Hungary issued a decree in 1342 that ordered the establishment of gold-testing houses and described the method of testing using the fire assay method of Pliny. Gold and silver were separated by cupellation with lead and then parted by cementation with powdered brick, iron oxide, and salt. Later when mineral acids became available, in the Middle Ages, parting was by boiling with *aqua fortis* (nitric acid). Details were given by Biringuccio, in *Pirotechnica*, 1540, and by Agricola, in *De Re Metallica*, 1566; both are based on the earlier *Pro-bierbuchlien*, 1510.

Little has been recorded on the early examination of solutions. The oldest record comes from Pliny in *Naturalis historiae libre 33* in which mention is made of the detection of the adulteration of copper sulfate by iron sulfate by using a strip of papyrus soaked in an extract of gall-nuts. If the 'vitriol' solution was adulterated with iron, the papyrus turned black.

Methods of wet analysis were slow to develop as lack of acids made it difficult to bring many materials into solution. Mineral acids were not available until the Middle Ages, then first prepared by unknown alchemists. Nitric acid was first mentioned in the thirteenth century as *aqua fortis* (strong water) by which silver could be separated from gold. It was the availability of mineral acids that enabled wet methods of analysis to be developed for a wide range of materials.

## Qualitative Analysis

A number of qualitative analytical reactions were known and used for identifying substances in solution as early as the seventeenth century. It was known to Boyle that solutions of some metals gave precipitates with alkalis, that a solution of silver becomes turbid on addition of common salt, and that a solution of copper turns dark blue on addition of ammonia. Boyle was the first to mention that some plant extracts (violet, cornflower, damask-rose, black cherry, etc.) change color in the presence of acids or alkalis. This observation contributed greatly to the development of the concept of acids and bases. A great deal of knowledge on qualitative analytical reactions gradually accumulated from the examination of mineral and medicinal waters. Boyle was the first to examine the use of hydrogen sulfide for the detection of copper and arsenic. He also made

**Figure 1** Gold assay by cupellation. From Biringuccio: *Pirotechnica* 1540.

experiments to assess the sensitivity of reactions and estimate limits of detection.

In the eighteenth century, a new analytical device appeared for carrying out qualitative analysis by a fire process that was borrowed from the glass industry by unknown analysts. The device was the blow pipe; using charcoal the reduction processes of metallurgy were scaled down. It was with this device, now more or less forgotten, that a number of chemical elements, for example, tantalum, were discovered in the eighteenth century and at the beginning of the nineteenth century.

Fusion with soda/potash was first used for analytical purposes in the eighteenth century. Wet methods were also developed, new reactions were introduced for detecting newly discovered metals (e.g., precipitation with sulfate for barium, oxidation to the dioxide for manganese), and newly found compounds were used as reagents (e.g., iron(II) cyanide for iron, oxalic acid for calcium, and hydrogen fluoride for silicic acid). Bergman was the first to attempt a comprehensive summary and systemization of analytical procedures in his books on water analysis, ore analysis, and on the examination of precious stones and minerals. He used 20 reagents in water analysis; among them were litmus for testing for acidity, barium chloride for sulfate, lime water for carbon dioxide, mercury nitrate for alkaline compounds, silver nitrate for chloride and sulfur, and soap solution for 'water hardness'. He also noted the sensitivity, preparation, and purification of reagents. Surprisingly, he did not use hydrogen sulfide, the use of which seems to have been forgotten. Most probably it was Winterl who reintroduced hydrogen sulfide for the detection of metals. Bergman's work was followed up and extended by Kirwan.

Rose, in his book *Handbuch der analytischen Chemie* published in 1829, first classified qualitative analytical methods according to elements and not according to the natural substances to be analyzed. This concept was further developed by Fresenius into the now classical method of ion detection by separating metal ions into five groups, described in *Anleitung zur qualitative chemischen Analyse*, 1841. The first synthetic ion-specific organic reagent was the mixture of sulfanilic acid and 1-naphthylamine, the Griess-Ilosvay reagent for nitrite ion, introduced in 1889.

Fresenius founded the first journal devoted entirely to analytical chemistry, *Zeitschrift für analytische Chemie*, in 1862 (Figure 2). This was followed in 1876 by *The Analyst*. Rational explanations for reactions entered analytical chemistry from physical chemistry, an approach pioneered from the 1890s by Ostwald.

**Figure 2** Title page of volume 1 of the world's first journal solely devoted to analytical chemistry. It continues today after mergers with *Analysis* and with *Química Analítica* as *Analytical and Bio-analytical Chemistry*.

## Gravimetric Analysis

Initial data concerning gravimetry were based on the observation that equal amounts of an element produce the same amounts of precipitate with a given reagent, and are to be found in the literature of the eighteenth century. Much of these data refer to the determination of silver in the form of silver chloride. Bergman in *Docimasia humida*, 1780, gave a table of how many parts of product are obtained from 100 parts of metals when precipitated by various reagents. Some of his results were remarkably good. The results of gravimetric analysis led to the laws of combining weight ratios and later were used to determine atomic weights.

By the late 1800s, the technique of gravimetric analysis was more or less developed and has not changed very much since then. Precipitates were mainly ignited to constant weight; porcelain crucibles were used after 1800, platinum crucibles became readily available commercially from about 1820.

Previously results had to be corrected for the weight of the ash of the filter paper. 'Ash free' filter paper was first prepared by Austen in 1878, the same year as Gooch devised the version of the filter crucible that still bears his name. Sintered-glass crucibles came into use in the 1920s. The introduction of electric drying ovens made the controlled drying at lower temperatures of precipitates feasible. Measurement of the loss of weight of a precipitate with controlled rise in temperature, thermogravimetric analysis, owed much from 1940 onwards to Duval. Classical gravimetric analysis had a renaissance in the 1950s from the development of reagents to produce precipitant species at controlled rates in 'precipitation from homogeneous solution'.

### Volumetric Analysis (Titrimetry)

Volumetric analysis (titrimetry) was developed as a control method in the textile industry in the eighteenth century for determining potash, sulfuric acid, and, later, hypochlorite, all solutions used in textile bleaching. The first methods developed were for practical purposes, to control the 'goodness' (in French, *titre*) of solutions rather than to determine accurate concentrations. The Scottish chemist Home in *Experiments on Bleaching*, 1756, described a method for testing the 'goodness' of potash, in which nitric acid of a given dilution (1–6) was added by teaspoonful to 1 drachm of potash until the effervescence ceased. If less than 12 teaspoonful of the acid mixture were required the potash was not considered suitable for bleaching. In 1767, Lewis used litmus paper instead of cessation of effervescence to indicate completion of reaction. He determined the amount of titrant by weighing. He determined the acid titer using pure potassium carbonate, thus making absolute determinations.

Guyton de Morveau was the first to carry out a precipitation titration, 1782. Hydrochloric acid was titrated with lead nitrate solution until precipitate formation ceased. The first redox titration was due to Descroizilles, around 1788, who used indigo solution to determine the strength of sodium hypochlorite solution used for textile bleaching. The end point was indicated by the persistence of color of the titrant, indigo. This method was not absolute but it was suitable for testing the 'goodness' of the bleaching solution. Descroizilles also worked on improvements for the titration of potash. In this work he recommended the use of specially designed laboratory glassware, describing what were probably the first forms of burette, pipette, and volumetric flask (Figure 3).

Gay-Lussac improved the design of these devices and was the first to use the names burette, pipette, and normal solution (Figure 4). The latter term did not mean what it means now but only a solution of a given concentration. At the time the concentration of titrants used in various determinations was chosen arbitrarily, so that the volume of titrant consumed by a certain amount of sample indicated directly the quality, expressed in arbitrary degrees. Some of the degrees used then still remain in use, for example, those used for 'water hardness'.

Ure suggested in 1844 that concentrations of titrant solutions should be related to the equivalent weights in order to produce a general 'acidimeter'. As he used British units his suggestion was not adopted

**Figure 3** Descroizille's volumetric flask, burette, called a 'bertholli-mètre', and pipette. (From Descroizille (1795) *Arts et Man.* 1 (an III), pp. 256–276.)

internationally. In 1855, Mohr introduced the concept of normal solutions that contain the equivalent weight of a substance in 1 l, a concept eventually accepted universally.

Titrimetric analysis became a precise and accurate method of scientific standard primarily due to the activities of Gay-Lussac and Mohr. Mohr critically re-examined the majority of analytical procedures known at the time. In his immensely successful book *Lehrbuch der chemisch-analytischen Titrimethode*, first published in 1855 and in numerous editions until 1936, he gave

ongoing summaries of developments up-to-date. Some of the important achievements in the various areas of titrimetry are briefly indicated below.

Potassium hydrogencarbonate, which is still used for standardization in acid–base titrations, was introduced by Than in 1860. The various redox titrants, their originators, and the dates are listed in Table 1.

In the field of redox titrations, most of the problems were connected with indicators. Hence, iodometry and permangometry, which are self-indicating methods, became the most widely used. The first redox indicator, diphenylamine, for the dichromate titration of iron(II), was introduced by Knop in 1924.

Titrimetric measurements based on the formation of soluble complexes had little importance for a long time. The first such method, the titration of chloride by mercury(II) using urea as indicator, was introduced by Liebig in 1851. The introduction of chelating agents and metallochromic indicators was the greatest advance in titrimetric analysis in the twentieth century and is linked with the name of Schwarzenbach (1946). Titration in nonaqueous media is important for functional group determinations of organic compounds. The first titration in this area was that by Vorländer, who, in 1903, determined aniline by titration with hydrochloric acid in benzene.

**Figure 4** Gay-Lussac's titrimetric equipment. (From Gay-Lussac (1824) *Annales de Chimie* 26: 162.)

## Organic Elemental Analysis

Organic substances have been distinguished from inorganic ones since the seventeenth century. Chemists in the eighteenth century, starting with Lavoisier, who recognized the role of oxygen in combustion, studied the combustion products of organic substances. At first it was believed that organic compounds were mainly composed of carbon, hydrogen, and oxygen. Lavoisier was the first to carry out experiments to determine the composition of organic substances by measuring the volume of gases produced by combustion and the subsequent absorption of carbon dioxide and measurement of the decrease in volume

**Table 1** Developments in the field of redox titration

Titrant	Originators	Year of first use
Iodine solution	Du Pasquier	1840
Iodometric determination based on the measurement of iodine liberated from iodide	Bunsen	1853
Potassium permanganate standard solution	Margueritte	1846
Potassium dichromate standard solution	Schabus and Penny, independently	1850
Sodium thiosulfate standard solution	Schwarz	1853
Potassium bromate standard solution	Györy	1893
Ascorbic acid standard solution	Erdey	1950

(1789). For methyl alcohol, he found the weight ratio of hydrogen to carbon to be 3.6:1. Considering the experimental difficulties for the first such determination, it was reasonably close to the correct value, 4:1.

Refinements to his ideas and improvements in the apparatus brought improved results. Gay-Lussac and Thenard used vertical combustion tubes. Berzelius used a horizontal tube and determined hydrogen by condensing the bulk of water and absorption of the residual in calcium chloride. Later, Leibig instead of measuring gas volumes used solid absorbents for water and for carbon dioxide (1831). His apparatus (Figure 5) can be considered as the prototype of the combustion devices still in use. Pregl succeeded in miniaturizing the apparatus in the first years of the twentieth century following Kuhlmann's production for him of a sufficiently sensitive microbalance. Pregl received the Nobel prize for chemistry in 1923. In the nineteenth century, one way of determining nitrogen was by gasometry after combustion. This is still done in essentially the same way as was introduced by Dumas in 1831, although on a microscale. The basis of the chemical determination of nitrogen is by its transformation into ammonia, a method first suggested by Dumas but whose practical realization was due to Varrentrap and Will (1841). After boiling with barium hydroxide solution the ammonia formed was precipitated with platinum chloride and weighed. This method was soon replaced by Kjeldahl in 1883, by digestion in sulfuric acid in the presence of a catalyst, making alkaline and distilling out the ammonia, absorbing in dilute sulfuric acid, and titration of the excess acid. The method has been improved and automated systems are in current routine use.

Elemental organic analysis together with knowledge of the reactions used was, till the advent of structure-sensitive spectroscopic techniques, the normal method of identification and determination of the products of organic synthesis.

However, elemental analysis alone was not sufficient to allow the identification and control of

natural and agricultural products, for which characteristic functional groups need to be determined. The search for suitable reactions and the systematization of these reactions was a long and complex task. The first book in this complex and heterogeneous area was that by Mullikan, *Identification of Pure Organic Compounds*, 1904.

During the last few decades organic analysis has undergone fundamental changes. Chemical methods have reduced importance and automated physical methods are now regarded as essential to confirm structures.

## Optical Methods

Boyle was the first to use flame coloration for analytical purposes, the detection of adulteration of silver by copper. Maggraff was a pioneer both in using optical devices and the characteristic optical behavior of materials for analytical purposes. He was probably the first to use a microscope for identifying substances when, in 1747, he showed that cane sugar was identical to beet sugar. He also made early use of the characteristic colors imparted to flames and distinguished potash from soda.

The development of emission spectroscopy was a long process initiated by Descartes in 1637 with his illustration that white light can be decomposed into its components with a prism. Several scientists later observed dark lines in the solar spectrum (e.g., Wollaston in 1802). Their constancy was noted and they were mapped in detail by Fraunhofer in 1814. He also noted the appearance of colored, changing lines from other sources. Talbot in 1826 correlated the appearance of some lines with the presence of certain elements. Similar observations were described later by other scientists without arousing much interest at the time. In this context the work of Alter is significant, he produced the first spectral atlas, a tabulation relating spectral lines to chemical elements, in 1854.

Emission spectroscopy achieved complete scientific recognition owing to the work of Bunsen and Kirchhoff, who, in their famous lecture in 1859, described their construction of the spectroscope and its application to the identification of elements (Figure 6). They built this by quite simply using two telescopes, one without the eyepiece lenses, which were replaced by a slit, a prism, and a mirror. Various flames, in which materials were suspended, were used for excitation. In later papers Kirchhoff explained the reasons for the appearance of dark and bright lines in the solar spectrum, and Bunsen proved the power of the method by reporting the discovery of two new elements, cesium and rubidium. In the following

**Figure 5** Leibig's combustion apparatus for organic elemental analysis. (From Liebig (1837) *Anleitung zur Analyse organischer Körper*.) The small triangular glass bubbler contained potassium hydroxide solution to absorb carbon dioxide. The horizontal tubes on each side of the bubbler contained anhydrous calcium chloride to absorb water.

**Figure 6** Kirchhoff and Bunsen's spectroscope: (A) a box, blackened interior; (B) and (C) small telescopes, (B) contains a metal sheet with slit, replacing the eye-piece; (D) light source in front of the slit, Bunsen burner and (E) platinum wire for holding material to be examined; (F) a hollow glass prism filled with carbon disulfide; (G) turnable mirror. (From Kirchhoff and Bunsen (1860) *Poggendorfs Annalen* 110: 160.)

decades mainly nonanalytical scientists were concerned with improvements to the technique. Astronomers made major contributions since spectroscopy was as important to their field as in chemistry. The most important and time-consuming task was to identify the wavelengths of the characteristic lines of all the elements.

Spectroscopy was for a long time only used as an efficient tool for qualitative analysis. It was only in the early twentieth century that it was used in quantitative analysis. Pioneering work was done in this field by Hartley, followed by Gerlach and Schweitzer, who developed the method of homologous line pairs based on the comparison of the line-blackness on a photographic plate.

Starting with the rather unreliable comparison by human eye and then by photography, emission spectrum evaluation made spectacular improvements as a result of electronics and instrumentation, via photoelectric line densitometers introduced by Lundegårdh in 1929, to the commercial manufacture of today's direct reading spectrometers.

The history of flame spectroscopy is difficult to separate from the other types of emission spectroscopy, but it does have some unique features. The analytical use of flame spectra has a long history since the time of Bunsen and Kirchhoff. De Gramont made a major contribution in 1923 by introducing the very hot oxygen-acetylene flame. Lundegårdh constructed the first flame photometer in 1928 with an atomizer (now called a nebulizer), a pressure control unit, and a photocell for detection. Nebulization was used as early as 1879, by Gouy when

investigating emission processes. The practical use of atomic absorption spectroscopy dates from Walsh's classic paper of 1955.

The first paper on X-ray emission spectroscopy with 'quantitative analysis' in the title was Heading's paper of 1922. In 1923, Coster and Hevesy discovered the element hafnium by this technique. However, owing to the experimental difficulties it was not widely used until improvements in radiation detection from radiochemical studies became available. With the development of scintillation counters it became a relatively simple and effective analytical technique, now known as X-ray fluorescence spectrometric analysis.

Electron microprobe analysis is based on excitation of an electron beam concentrated on a very small area (a few square micrometers) of a sample and examination of the X-rays produced. The method was pioneered by Castaing in 1949.

The history of light absorption methods is long and complicated. Without defining any law it was considered obvious that for colored compounds the intensity or depth of color was proportional to the concentration, and quantitative analyses were made by color comparison. The first such analysis was for iron in Tunbridge water, using tincture of galls, by Boyle in 1684. The method was rediscovered 150 years later by Lampadius for iron in 1838, and by Heine for bromide in 1845 using color comparison against standards in simple glass cylinders. Müller constructed the first colorimeter based on the use of a complementary colored glass filter at the base of a cylinder containing the solution, a smaller empty

cylinder was lowered into the solution and the depth to yield approximately white light was noted. Bouguer in 1729 and Lambert in a more detailed form in 1760 established the law describing how the intensity of light was reduced on passing through sheets of glass. In 1852, Beer extended the observations to colored solutions and, he also introduced the concept of the absorption coefficient. Vierordt was the first in 1870 to make a 'photometric' determination using the first instrument based on light intensity. His spectrometer slit had two halves: the light source was viewed through solution covering the lower part and empty cell the upper part. The upper slit was narrowed until the light intensity matched. From the relative slit widths the fraction absorbed by the sample was known. A simplified instrument with filters in place of the spectroscopy was built by Krüss. Measurements were also made by matching light in intensity by varying the depth through which the sample is viewed relative to the blank using Duboscq colorimeters. Berg introduced the first photoelectric colorimeter in 1911 although they did not come into common use till the mid-1920s.

Measurements in the ultraviolet range posed no particular difficulties but instruments only became widely available in the mid-1940s based on the design of Cary and Beckman in spite of the fact that the principles and practice of the method were fully developed at the start of the century.

Infrared radiation was discovered by Herschel in 1800. The bolometer detector (sensitive resistance thermometer) was invented by Langley and was used by him for studying the infrared spectrum of the sun in 1881. Coblentz in *Investigations of Infrared Spectra*, published in 1905, described the infrared spectrum of several hundred compounds, measured point by point using a custom-made instrument containing a rock-salt prism, a mirror spectrometer, and a radiometer detector. Each spectrum took 3–4 h to obtain. Infrared spectroscopy only began to develop in more routine use in the 1930s initiated by needs of the petroleum industry.

The polarization of light by certain crystals has been known for about a long time, as has the ability of some to rotate the plane of polarization of light. Biot in 1813 observed that some liquids and solutions behaved similarly. In 1828, Nichol constructed the prism that bears his name by cementing together with Canada balsam two halves of a split calcite spar crystal. It is probable that Ventzke was the first to use such prisms in 1842 to construct a polarimeter, used to determine the concentration of sugar solutions by measuring the angle of rotation of the plane of polarization. Polarimeters rapidly improved in design and were widely used in many countries where sugar

was subject to special taxation by revenue officers. The correlation of optical activity with the presence of an asymmetric carbon atom in dissymmetrical organic compounds was first made by Le Bel and van't Hoff in 1874. From the mid-1950s, Djerassi and his students studied the variation of rotation with wavelength in the vicinity of absorption bands, optical rotatory dispersion, for structural analyses.

## Electroanalytical Methods

Although chemical effects of an electric current were observed as early as 1800, immediately after the Volta column battery was invented, analytical applications of the phenomena took a long time to develop. Wolcott Gibbs weighed the amounts of metal deposited and, in 1864, he was the first to determine copper by electrogravimetry. Classen made many fundamental contributions to the study and development of the method and in 1882 published the first book on electrogravimetry, *Quantitative Analysis auf elektolytischen Wege*.

Coulometric titration is a direct application of Faraday's laws of electrolysis, it was first applied in this mode by Szebellédy and Somogyi in 1939.

The first potentiometric titration was carried out by Behrend in 1893 at Ostwald's Institute in Leipzig. He titrated mercury(I) nitrate with potassium chloride or with potassium bromide standard solutions using mercury electrode and a mercury/mercury(I) reference electrode. Behrend used a capillary electrometer to measure the electromotive force. The hydrogen electrode was also discovered in 1893 by Le Blanc. He did not, however, use it for analytical purposes but only for electrochemical investigations. Böttger, another student of Ostwald, was the first in 1897 to use a hydrogen electrode to follow an acid–base titration. Potentiometry was first applied to redox titrations by Crotonogino in 1900. He titrated iodide with potassium permanganate using a platinum indicator electrode. For many years potentiometry remained of theoretical interest only since it was difficult to carry out in practice. The first monograph on the topic, in 1923, was *Die elektrometrische Massanalyse* by Müller. It only became an accepted analytical technique after the appearance of commercial electronic instruments in the 1930s. In spite of this, several potentiometric procedures and end-point detection methods are much older than is commonly believed, their principles established early in the twentieth century.

Conductimetric titration techniques were developed as a result of studies by physicists, pioneered by Kohlrausch, who developed both the method and the

necessary instrumentation. Analytical chemists had only the task of finding suitable analytical applications. It is characteristic of analytical chemistry that it has frequently applied techniques originally developed in other areas of science for its own purposes. For conductivity this step was taken by Küster and Grütters in 1903 for the determination of acids and bases.

Oscillometric or high-frequency titration was invented simultaneously and independently by Foreman and Crisp and also by Jensen and Parrak in 1946. Inorganic ion-selective heterogeneous membrane electrodes were introduced for electrometric titrations by Pungor in 1961 and those with neutral organic complexing or ion-exchange compounds by Simon in 1966.

The first voltammetric method was polarography. Electrolysis at a dropping mercury electrode was first described by Heyrovsky in 1922, and the first polarograph constructed by Heyrovsky and Shikita in 1925. Heyrovsky was awarded the Nobel Prize in 1959. Further developments of the method are linked with the names of Matheson and Nichols (oscillopolarography), Heyrovsky (derivative polarography), and Barker (square wave and pulse polarography).

## Radiochemical Analysis

Radioactivity was a discovery that was soon brought into the arsenal of analytical chemistry. It is interesting to note that, as in some other fields, radiation from radioactive species was examined for analytical purposes in a variety of different ways at a time when they had little practical importance, because the radiation detectors were primitive and the field of potential applications limited owing to the small number of natural radionuclides. After the production of artificial radionuclides had started the importance of the earlier radiochemical methods increased rapidly and this field became one of the most powerful in trace analysis.

The analytical application of radionuclides, along with other applications in radioanalysis, results directly from Hevesy and Paneth's invention of radio-tracer and radio-indication techniques in 1912. They pointed out that the addition to a solution of an element of its radioactive isotope makes possible the identification and determination of the element. In their first application they labeled a solution of lead with radium-D, a natural radioactive lead isotope and determined the solubility of sparingly soluble lead salts.

Isotope dilution analysis is probably the most important radiochemical method. A radioactive isotope, whose specific activity is known, is added to a

sample. After a separation, which need not be quantitative, a pure sample is taken and the activity measured. The ratio of this activity to the initial activity (corrected for any decay), together with the weight of the sample, will give the amount of inactive element present in the initial sample. This concept was due to Hevesy. In the first application Hevesy and Hobbie determined the lead content of rocks, the separation was electrolytic, deposition of lead peroxide. The procedure has been simplified by the introduction of substoichiometric analysis by Starý and Ruzicka in 1961.

Radioactive reagents were pioneered by Ehrenberg in 1925 using reagents that contained a radionuclide, calculating the amount of sample from the precipitate or the filtrate after precipitation. The method was not used much until the ready availability of artificial radioisotopes. Radiometric titrations achieved greater popularity. In these methods either the titrand or the titrant may be labeled. The product of the reaction is separated from the solution, in simple cases as a precipitate or by extraction. Evaluation is carried out by a graphical method. The first example, a precipitation titration, was by Langer in 1941.

Radiochemical versions of many other techniques were soon developed, for example, paper chromatography, ion-exchange chromatography.

Activation analysis is the other field of radiochemical analysis that has become of major importance, particularly neutron activation analysis. In this method nuclear transformations are carried out by irradiation with neutrons. The nature and the intensity of the radiation emitted by the radionuclides formed are characteristic, respectively, of the nature and concentrations of the atoms irradiated. Activation analysis is one of the most sensitive methods, an important tool for the analysis of high-purity materials, and lends itself to automation. The technique was devised by Hevesy, who with Levi in 1936 determined dysprosium in yttrium by measuring the radiation of dysprosium after irradiation with neutrons from a Po-Be neutron source. At the time the nature of the radiation was characterized by half-life, and the only available neutron sources were Po-Be and Ra-Be, which were of low efficiency. Hevesy's paper was not followed up for many years. The importance of activation analysis increased dramatically after the emergence of accelerators and reactors in which almost all elements could be activated. Hevesy received the 1943 Nobel prize in chemistry for 'work on the use of isotopes as tracers in the study of chemical processes'.

For a long time only electroscopes were used for measuring radiation from radioactive sources. The first

counter was constructed in 1908 as a result of experiments of Rutherford and Geiger. The counter tube was improved by Geiger and Müller in 1928, and it was the most widely used detector in radiochemistry for decades. Scintillation detectors, which, with appropriate amplification and attenuation, enabled beta and gamma radiations to be recorded as functions of their energies, were developed soon after World War II. One of the best materials used for this purpose was a sodium iodide single crystal activated with thallium, first used by Hofstadter in 1948. With the rapid developments of electronics and transistor techniques, this detector became the basis of modern multichannel analyzers for beta and gamma spectrometry.

## Chromatographic Techniques

Chromatography was one of the most rapidly developing areas in the second half of the twentieth century that opened up new vistas, especially for the examination of complex organic materials. Although the method is in many ways new, its recent forms, its origin, and inventor cannot be identified with certainty as some experiments go back a long way. Methods that we now recognize as 'chromatographic' can be found in the literature of the nineteenth century. For example, Schönbein reported in 1861 when developing tests for ozone that the solvent precedes the dissolved substances and that different substances are drawn up the paper to varying degrees. His student Goppelsröder devoted his life to the elaboration of this so-called capillary analysis technique. He published many papers on the subject and summarized his studies in a monograph *Anregung zum Studium der auf Capillaritäts und Absorptionserscheinungen beruhenden Capillaranalyse* in 1906. Tswett came into the history of chromatography from botany. He used a column filled with inulin for separating plant pigments. In 1903, when passing leaf extracts through a column he found colored components situated in the form of discs at different parts of the column. He called the technique chromatography from the Greek word *chroma* for color. Although adsorption column chromatography proved to be effective for the separation of natural organic materials it only became of practical importance after it was used by Kuhn, Winterstein, and Lederer for the separation of carotenoids. This marked the beginning of the era of modern chromatography.

The amalgamation of the principle of countercurrent extraction and experience with adsorption chromatography led to the development of partition chromatography, an invention linked with the names

of Martin and Synge, who in 1941 used partition between chloroform and water retained in silica gel to separate components of protein hydrolysates. They jointly received the Nobel prize for chemistry in 1952. Paper chromatography, in which the support is paper, was later used by Gordon, Martin, and Synge (1943). For a while paper chromatography made much progress. Gas chromatography invented by Martin and James in 1952 developed more slowly at first due to difficulties with instrumentation. Paper chromatography gradually lost its importance, mainly due to the rapid development of thin-layer chromatography, following the advances made by Stahl that were published in his 1962 monograph.

Ion-exchange methods are also important in modern analytical chemistry. They now take the place of a number of complicated separations which in the past were achieved by series of precipitations. The ion-exchange properties of certain clay minerals were observed in the middle of the nineteenth century. The phenomenon was first utilized in industrial and agricultural processes, for example, for removing alkali from sugar beet liquors. Ion exchange was used for analytical purposes only at the end of World War I, when Folin and Bell (1917) bound ammonia in urine as ammonium in its separation from creatine using an artificial ion exchanger, synthetic aluminum silicate patented by Gans in 1905. Analytical applications of ion exchangers only really developed after ion-exchange resins were discovered. The first examples of such resins were made by Adams and Holmes in 1935. Since then, a wide range of ion-exchange resins have been produced commercially. The successful incorporation of ion exchangers into chromatography has enabled separations to be achieved that were not possible by other techniques, such as those for the rare earths and the radioactive materials in the Manhattan project. Possibly the first report of this method was made by Russel, Svartout, Hume, and Kettle in 1944, first published in the open literature in 1947. Ion-exchange chromatography received a boost and renewed interest in 1975 after Small, Stevens, and Bauman's incorporation of a suppressor column between the separator and a conductivity detector to increase sensitivity by reduction of the background.

Molecular sieves had been in use since the mid-1920s for chromatographic separations of small molecules. The application to water-soluble fragile materials of biological origin was the subject of intense activity after the discovery of cross-linked dextran gels by Porath and Flodin in 1957 in what became known as 'gel filtration' or size exclusion chromatography.

### Introduction

The analysis of steroid hormones and their semisynthetic analogs falls into a number of different areas, such as

1. Determination of steroid hormones, the intermediates of their biosynthesis and their metabolites, and the semisynthetic analogs and their metabolites in biological samples. This is of great importance in clinical biochemistry, diagnostics, therapeutic drug monitoring, doping control of athletes, and analytical control of meat products.
2. Structure elucidation of steroid hormone analogs (products and intermediates of synthetic drug research, impurities, degradation products, metabolites).
3. Assay of bulk hormone drugs and impurity determination.
4. Assay of hormone formulations, including stability assays.

Highly selective and sensitive methods are required to solve these problems; in the majority of cases the complex application of chromatographic, spectroscopic, and immunoassay methods is necessary.

### Main Types of Steroid Hormones and Their Semisynthetic Analogs

Steroid hormones can be classified into two main groups: sex hormones and corticosteroid hormones. Of the sex hormones, androgens are secreted mainly by the testes (main representative: testosterone), estrogens by the ovary (main representative: estradiol), and the gestogens (progestogens, progestins) by the corpus luteum (main representative: progesterone). Corticosteroid hormones are secreted by the adrenal cortex. One of the main representatives is cortisol (hydrocortisone). The structures of these hormones are given in **Figure 1**.

For drug therapy, native hormones have been replaced to a large extent by synthetic or semisynthetic derivatives that possess higher and more selective therapeutic potential. Some very important synthetic androgen analogs are the esters and the 17-methyl derivative of testosterone. Of the numerous related anabolic steroids, the esters of nandrolone (19-nortestosterone), methandienone (17 $\alpha$ -methyl-17-hydroxy-1,4-androstadien-3-one), stanozolol (17 $\alpha$ -methyl-2'H-5 $\alpha$ -androst-2-eno[3,2-c]pyrazol-17-ol, and trenbolone acetate (17 $\beta$ -hydroxy-4,9,11-estratrien-3-one acetate) are most frequently used.

Among the synthetic estrogens and gestogens, the 17 $\alpha$ -ethinyl-17-hydroxy derivatives merit special mention. The introduction of the ethinyl group greatly increases their hormonal potential, thus enabling their dose to be decreased (e.g., in contraceptive tablets) to the 10  $\mu$ g per tablet and 100  $\mu$ g per tablet level, respectively. Characteristic examples of this type are the estrogenic ethinylestradiol (17 $\alpha$ -ethinyl-1,3,5(10)-estratrien-3,17-diol) and the gestogenic norethisterone (17 $\alpha$ -ethinyl-17-hydroxy-4-estren-3-one), and norgestrel, the synthetic 13-ethyl analog of the latter.

The most important synthetic corticosteroid is prednisolone, which is the  $\Delta^1$  analog of cortisol.

### Introduction

The analysis of steroid hormones and their semisynthetic analogs falls into a number of different areas, such as

1. Determination of steroid hormones, the intermediates of their biosynthesis and their metabolites, and the semisynthetic analogs and their metabolites in biological samples. This is of great importance in clinical biochemistry, diagnostics, therapeutic drug monitoring, doping control of athletes, and analytical control of meat products.
2. Structure elucidation of steroid hormone analogs (products and intermediates of synthetic drug research, impurities, degradation products, metabolites).
3. Assay of bulk hormone drugs and impurity determination.
4. Assay of hormone formulations, including stability assays.

Highly selective and sensitive methods are required to solve these problems; in the majority of cases the complex application of chromatographic, spectroscopic, and immunoassay methods is necessary.

### Main Types of Steroid Hormones and Their Semisynthetic Analogs

Steroid hormones can be classified into two main groups: sex hormones and corticosteroid hormones. Of the sex hormones, androgens are secreted mainly by the testes (main representative: testosterone), estrogens by the ovary (main representative: estradiol), and the gestogens (progestogens, progestins) by the corpus luteum (main representative: progesterone). Corticosteroid hormones are secreted by the adrenal cortex. One of the main representatives is cortisol (hydrocortisone). The structures of these hormones are given in **Figure 1**.

For drug therapy, native hormones have been replaced to a large extent by synthetic or semisynthetic derivatives that possess higher and more selective therapeutic potential. Some very important synthetic androgen analogs are the esters and the 17-methyl derivative of testosterone. Of the numerous related anabolic steroids, the esters of nandrolone (19-nortestosterone), methandienone (17 $\alpha$ -methyl-17-hydroxy-1,4-androstadien-3-one), stanozolol (17 $\alpha$ -methyl-2'H-5 $\alpha$ -androst-2-eno[3,2-c]pyrazol-17-ol, and trenbolone acetate (17 $\beta$ -hydroxy-4,9,11-estratrien-3-one acetate) are most frequently used.

Among the synthetic estrogens and gestogens, the 17 $\alpha$ -ethinyl-17-hydroxy derivatives merit special mention. The introduction of the ethinyl group greatly increases their hormonal potential, thus enabling their dose to be decreased (e.g., in contraceptive tablets) to the 10  $\mu$ g per tablet and 100  $\mu$ g per tablet level, respectively. Characteristic examples of this type are the estrogenic ethinylestradiol (17 $\alpha$ -ethinyl-1,3,5(10)-estratrien-3,17-diol) and the gestogenic norethisterone (17 $\alpha$ -ethinyl-17-hydroxy-4-estren-3-one), and norgestrel, the synthetic 13-ethyl analog of the latter.

The most important synthetic corticosteroid is prednisolone, which is the  $\Delta^1$  analog of cortisol.

**Figure 1** Structures of several steroid hormones.

Highly active derivatives can be derived from prednisolone by introducing halogens, mainly fluorine, at positions 9 and 6, methyl groups at 6 and 16, a hydroxyl group at 16, etc. For instance, dexamethasone and betamethasone are the 16 $\alpha$ - and  $\beta$ -methyl derivatives of 9 $\alpha$ -fluoroprednisolone, respectively, and triamcinolone is the 16 $\alpha$ -hydroxy derivative of 9 $\alpha$ -fluoroprednisolone.

## Methods Used in the Analysis of Steroid Hormones

### Classical Methods

Due to the lack of suitable functional groups in steroid hormones, titrimetry has never played an important role in steroid hormone analysis. Of the several indirect methods, however, one is still widely used: all pharmacopoeias contain methods for the determination of ethinyl steroids on the basis of the exchange of the acetylenic hydrogen for silver ions and the titration of the liberated acid with standard sodium hydroxide.

$\Delta^4$ -3-oxo and  $\Delta^{1,4}$ -3-oxo groups can be reduced at the dropping mercury electrode in the range between  $-1.22$  and  $-1.37$  V in the concentration range of  $10^{-3}$  mol l $^{-1}$ , enabling their polarographic determination in drug formulations. Although with the aid of modern polarographic techniques, especially differential pulse polarography, the sensitivity can be increased 10- to 100-fold, even this sensitivity and

the poor selectivity preclude application of this technique to the analysis of biological materials.

### Spectroscopic Methods

**Ultraviolet-visible spectrophotometry** Due to the presence of either an unsaturated oxo group or a phenolic ring in their molecules, the majority of steroid hormones absorb strongly in the ultraviolet (UV) region (see Table 1). The UV spectra of steroid hormones are of limited importance in elucidating their structure, but enable their moderately selective quantitative determination in simple pharmaceutical formulations.

To enhance the applicability of UV spectrophotometry in pharmaceutical steroid analysis by increasing its selectivity and sensitivity, various methods have been developed based on chemical reactions leading to colored derivatives. Although their importance has decreased considerably, some of these methods are still in use in pharmacopoeias, mainly in the assay of formulations. For example, the  $\Delta^4$ -3-oxo and  $\Delta^{1,4}$ -3-oxo steroids can be determined as isonicotinoyl hydrazones ( $\lambda_{\max}$  380 and 410 nm;  $\epsilon \sim 11\,500$  and  $17\,000$ , respectively). The dihydroxyacetone side chain of corticosteroids at C17 reduces tetrazolium reagents to colored formazans ( $\lambda_{\max}$  485 and 525 nm with triphenyl tetrazolium chloride and Tetrazolium Blue reagents, respectively;  $\epsilon \sim 16\,000$  and  $24\,000$ ), thus creating the basis for a stability-indicating indirect colorimetric assay. Corticosteroids

**Table 1** UV spectral data of some important groups of steroid hormones and their synthetic analogs (solvent: ethanol)

Functional group	$\lambda_{\max}$ (nm)	$\epsilon$ ( $\text{l mol}^{-1} \text{cm}^{-1}$ )	Occurrence	Typical derivatives
$\Delta^4$ -3-Oxo	240	17 000	Androgens, anabolics, gestogens, corticosteroids	Testosterone, nortestosterone esters, progesterone, cortisol
$\Delta^{1,4}$ -3-Oxo	243	16 000	Anabolics, corticosteroids	Methandienone, prednisolone
$\Delta^{4,6}$ -3-Oxo	285	25 000	Gestogens	Megestrol acetate
$\Delta^{4,9,11}$ -3-Oxo	341	28 000	Anabolics	Trenbolone
1,3,5(10)-Triene-3-ol			Estrogens	Estrone, estradiol, ethinylestradiol
Neutral	280	2 000		
Alkaline	300	2 800		
1,3,5(10)-Triene-3-alkoxy	287	1 900	Estrogens	Mestranol
	278	1 750		
1,3,5(10)-Triene-3-acyloxy	268	800	Estrogens	Estradiol dipropionate

$\epsilon$ , molar absorptivity;  $\lambda_{\max}$ , wavelength of maximum absorbance.

are also determined with the phenylhydrazine/sulfuric acid reagent ( $\lambda_{\max}$  410 nm;  $\epsilon \sim 28\,000 \text{ l mol}^{-1} \text{ cm}^{-1}$ ).

Enzymatic methods making use of the redox reactions of steroids and the measurement of NADH at 340 nm or other suitable colorimetric indicators greatly enhance the utility of spectrophotometry and enable their use in bioassays.

**Fluorimetry** Of the steroid hormones, estrogens, having a phenolic ring, possess natural fluorescence (excitation  $\sim 284$  nm, emission in the range 310–327 nm). The intensity of this relatively weak fluorescence is sufficient for the determination of estrogens in contraceptive pills even at the pharmacopoeia level, especially in the liquid chromatography (LC) assay of the pills using fluorescence detector.

Visible fluorescence and much higher intensity can be obtained by using various chemical reactions. These may be characterized by the high concentration of mineral acids in the reagents and the complex mechanism of the reactions. It is mainly estrogens that can be determined in this way, but sensitive methods are available for the determination of other groups of steroid hormones also. The high sensitivity of these methods enables them to be used in the analysis of biological samples, but these methods are being replaced by the even more sensitive and selective chromatographic and immunological methods.

**Infrared (IR) spectroscopy** In the early period of steroid research, IR spectroscopy was the main method for the structural elucidation of steroids. Although the importance of this technique in the structural elucidation of steroids has decreased considerably, it still retains some of its importance.

IR spectroscopy is widely used for the identification of steroids: it has completely replaced the classical color reactions used in earlier editions of the pharmacopoeias. It is also useful for the identification and characterization of polymorphic modifications, whose occurrence is quite common among steroid derivatives.

In the majority of cases the potassium bromide disk technique is used (see Table 2), but many examples can also be found in the literature about the application of the Nujol mull method. The use of solution spectra is usually restricted to the less important quantitative analytical applications.

**Nuclear magnetic resonance (NMR) spectroscopy** Since its introduction into the structural analysis of steroids about half a century ago, NMR spectroscopy has become the most powerful technique in this field. Even the age-old 'bottleneck' of NMR, i.e., the need for relatively large sample quantities, is gradually disappearing: continuing improvements in magnetic field homogeneity and strength as well as in hardware (e.g., low-noise electronic elements, superconducting probes, or probes employing high-speed magic-angle sample spinning) enable the sample quantity to be reduced to the microgram level.

Even one-dimensional (1D)  $^1\text{H}$  NMR spectra are often adequate to deduce some delicate configurational and conformational characteristics of a molecule. Such features are inferred from the chemical shifts and coupling constants of the respective protons as well as from the position of the easily detectable singlets of the C18 and C19 angular methyl groups. The use of the nuclear Overhauser effect (NOE) and various multipulse NMR techniques enable the solving of even more difficult problems.

**Table 2** Some characteristic IR bands of steroids

Group	Character of the band	Average wavenumber ( $\text{cm}^{-1}$ )	Intensity <sup>a</sup>
Bare steroid skeleton	$\nu_{\text{as}}$ ( $\text{CH}_3$ , $\text{CH}_2$ )	2950	s
	$\nu_{\text{sy}}$ ( $\text{CH}_3$ , $\text{CH}_2$ )	2880	s
	$\nu_{\text{sy}}$ ( $\text{CH}_3$ )	1380	m

	$\gamma$ ( $=\text{C}-\text{H}$ )	880	m
	$\nu$ ( $\text{C}=\text{O}$ )	1660	s
	$\nu$ ( $\text{C}=\text{C}$ )	1620, 1605	m, w
1,4-Diene-3-oxo	$\gamma$ ( $=\text{C}-\text{H}$ )	900	m

<sup>a</sup>s, strong; m, medium; w, weak; as, asymmetrical valence vibrations; sy, symmetrical valence vibrations.

This success of  $^1\text{H}$  NMR spectroscopy is all the more remarkable since the majority of the protons in steroids belong to skeletal methylene and methine groups, which give a crowded group of only partly resolved signals in the range of 1–2.5 ppm if traditional, low-, or medium-resolution instruments are used. (Using high-resolution, e.g., 900 MHz instruments even skeletal proton signals are distinguishable.) In contrast, the very wide range of chemical shifts in the  $^{13}\text{C}$  NMR spectra of steroids ( $\sim 220$  ppm, compared to the 10 ppm range in  $^1\text{H}$  NMR) enables the signals of all the 18–27 carbon atoms to be resolved and assigned. The assignment is greatly facilitated by the application of, for example, the DEPT pulse sequence technique, while for the assignment of both the  $^1\text{H}$  and  $^{13}\text{C}$  NMR signals  $^1\text{H}-^1\text{H}$  COSY,  $^1\text{H}-^{13}\text{C}$  COSY (HETCOR), and various long-range correlation techniques are successfully used. The application of modern 2D and 3D techniques employing pulsed field gradients and inverse detection enables the full assignment of spectra and thus aids rapid structure elucidation. Some of these techniques are g-DQF-COSY, g-HMQC, g-HMBC, g-HSQC-TOCSY, and DPFGE-NOE.

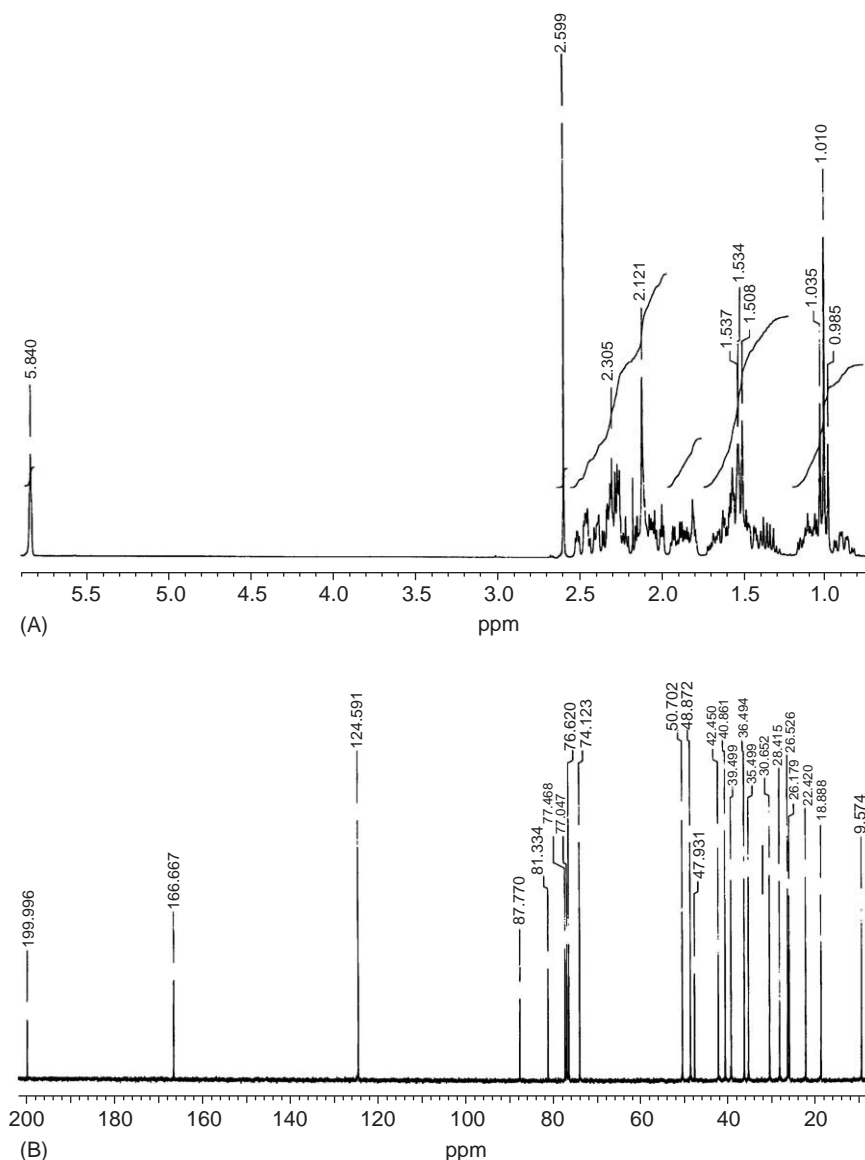

Figures 2 and 3 show the  $^1\text{H}$  and  $^{13}\text{C}$  spectra of norgestrel and the assignment of the signals.

**Mass spectrometry** Next to NMR spectroscopy in importance, mass spectrometry (MS) is the most

effective and most widely used technique for the structural elucidation of steroids.

The majority of steroid hormones and their synthetic analogs afford interpretable molecular ions and fairly characteristic fragmentation patterns, if the classical electron ionization technique in positive ion mode is used. Therefore, the latter is a very powerful method for structural elucidation. (A typical mass spectrum and fragmentation pattern are shown in Figures 4 and 5.) There are various possibilities for extending the utility of MS to less stable and less volatile steroids. With the aid of chemical derivatization (acetylation, trimethylsilylation, butyldimethylsilylation, etc.), their thermal stability and volatility can be increased. Chemical ionization affords molecular ions, even in the case of less stable steroids, but sacrifices at the same time the information afforded by fragmentation. With the aid of various field desorption and fast-atom bombardment techniques, highly polar steroids and their high relative molecular mass derivatives, such as conjugates (sulfates, glucuronides) and glycosides, can be analyzed.

Although generally, NMR spectroscopy affords more structural information, the great advantages of MS are its much higher sensitivity (enabling mass spectra to be obtained in the picogram range) and the possibility of coupling it with highly efficient chromatographic techniques (e.g., gas chromatography (GC)

**Figure 2** NMR spectra of norgestrel. Solvent/reference:  $\text{CDCl}_3/\text{TMS}$ . (A)  $^1\text{H}$  NMR spectrum; (B)  $^{13}\text{C}$  NMR spectrum.

**Figure 3** Assignment of the NMR signals of norgestrel in ppm. The upper (or single) values are the chemical shifts of the respective carbon nuclei from the  $^{13}\text{C}$  spectrum, while the lower values (in parentheses) are the assigned proton shifts in the  $^1\text{H}$  spectrum. Solvent/reference:  $\text{CDCl}_3/\text{TMS}$ . (Courtesy of G. Balogh, Chemical Works of Gedeon Richter Ltd., Budapest.)

and HPLC) for both structural elucidation and quantification. GC-MS is a reference method in clinical steroid analysis; the potential of LC-MS, especially in the highly sensitive electrospray ionization mode, is still far from exhausted.

**Other methods for structure elucidation** Optical rotatory dispersion and circular dichroism spectroscopy are important methods for solving stereochemical problems in the steroid field. Moreover, thanks to the relatively rigid structure of the steroid skeleton and its chromophoric groups, steroids often serve as model compounds for such investigations. Specifically, the Cotton effect is easily observable in the steroid field.

**Figure 4** Electron impact mass spectrum of  $\Delta^{8(14)}$ -norgestrel (17 $\alpha$ -ethinyl-17-hydroxy-13-ethyl-gona-4,8(14)-dien-3-one).

**Figure 5** Fragmentation of  $\Delta^{8(14)}$ -norgestrel. Ionization voltage, 70 eV. (Courtesy of É. Csizér, Chemical Works, Gedeon Richter Ltd., Budapest.)

X-ray diffractometry, which requires only a single crystal of the analyte for molecular structure elucidation, is also used for the solution of the most difficult problems in the investigation of steroids. This is illustrated by atlases containing over 400 steroid structures. The potential of this technique in the investigation of receptor binding of steroid hormones merits special mention.

**An example of the application of spectroscopic techniques** The structure elucidation of an impurity in norgestrel detected by reversed-phase LC at a relative retention of 0.90 was carried out as follows.

The UV spectrum recorded by the liquid chromatograph's diode array UV detector shows an intense maximum at 236 nm. This indicates that the impurity contains the 4-ene-3-oxo moiety. However, the slightly hypsochromic shift (see Table 1), and especially the broadening of the peak as compared to that of norgestrel, indicate the presence of a double bond in the skeleton, presumably in the 8(14) position, which is not in conjugation with the

4-ene-3-oxo group but affects its conformation ('through-space conjugation'). The mass spectrum (obtained from GC-MS studies), with its molecular peak at  $m/z$  310, and the fragmentation as shown in Figure 5, indicate a norgestrel structure with a second double bond in ring A, B, or C. In order to obtain convincing evidence regarding the location of the double bond, a few milligrams of the impurity are isolated by preparative LC.

The IR spectrum of this sample, with its bands characteristic of the 4-ene-3-oxo group (1651 and 1622  $\text{cm}^{-1}$ ), 17-ethinyl group (3277 and 2100  $\text{cm}^{-1}$ ), and the 17-hydroxy group (3344 and 1089  $\text{cm}^{-1}$ ) (see Table 2), also indicates a 'norgestrel-like' structure but with no data with respect to the second double bond. The  $^1\text{H}$  NMR spectrum alone does not afford direct data for the location of the second double bond either: no protons are attached to carbon atoms of the second double bond. Therefore, its position could be 8(9), 8(14), or 9(10). The latter can be precluded on the basis of the above-mentioned UV spectrum. Convincing evidence for the location of the double bond in the 8(14) position is furnished by the joint application of  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectroscopy using 2D homonuclear and heteronuclear correlation experiments: (1) mapping the  $^1\text{H}$ - $^1\text{H}$ ,  $^1\text{H}$ - $^{13}\text{C}$ , and long-range  $^1\text{H}$ - $^{13}\text{C}$  coupling networks in the molecule ( $^1\text{H}$ - $^1\text{H}$  COSY, HETCOR, and FLOCK) and (2) comparing the  $^{13}\text{C}$  chemical shifts with those of norgestrel (see Figure 3). The most important  $^{13}\text{C}$  shifts in this regard are:

C8 129.3 ppm  
C9 42.3 ppm

C10 45.2 ppm  
 C13 49.2 ppm  
 C14 137.2 ppm  
 C15 24.4 ppm  
 C16 37.1 ppm

### Chromatographic Methods

**Thin-layer chromatography** Thin-layer chromatography (TLC) is very important in steroid analysis. The apolar skeletons and polar substituents of steroids make them good models for separation studies.

A variety of adsorbents have been successfully applied to the separation of steroids; in the majority of cases silica gel plates have been used. Although the separation power of these techniques does not approach that of the most developed forms of GC and LC, in practice most separation problems can be solved using TLC (especially by using the overpressure and high-performance variants of the method). Most of the steroid hormones (bearing either the 4-ene-3-oxo or phenyl group) strongly absorb UV radiation, thus enabling their detection at the ng level. A variety of spray reagents are available (mostly containing various mineral acids) to enhance detectability and to increase sensitivity.

The main field of application of TLC is the rapid characterization of steroid mixtures and checking of the purity of bulk steroid hormones. For the latter purpose the pharmacopoeias widely recommend the semiquantitative estimation of impurities based on visual comparison of their spots with those of reference materials.

The early quantitative applications of TLC in steroid hormone analysis were based on spot elution followed by photometric measurement; this technique is still mentioned in some cases in pharmacopoeias. *In situ* densitometry, making use of the absorption of the colored zone (or fluorescence) that forms in the course of the reaction with spray reagents, is the basis of a great variety of methods. The linear range is usually in the region of 10 ng, but measurement of the fluorescence enables the limit of determination to be lowered to the subnanogram range. These methods are almost equivalent alternatives to the other chromatographic techniques in pharmaceutical steroid analysis, but they are only of secondary importance in the analysis of biological samples.

**Gas chromatography** The introduction of GC into steroid analysis in the beginning of the 1960s revolutionized the field. The high resolving power (especially of capillary GC) and the high sensitivity

attainable (especially with the electron capture and MS detectors) enabled hitherto unsolvable problems to be solved (e.g., the separation and quantification of minor steroid components in serum). The methodologies also found wide application in pharmaceutical steroid analysis.

The great dilemma of the GC analysis of steroids is whether to use derivatization or not. In the case of thermally unstable steroids, the answer is unequivocally yes. Steroids of this type are mainly the corticosteroids, containing the unstable  $\alpha$ -ketol side chain. Of several possibilities, double derivatization to form the methoxime trimethylsilyl derivatives is the most widely used (see reaction [I]):

Most of the other steroid hormones are sufficiently stable and volatile to be chromatographed without decomposition, and no derivatization is needed in the majority of pharmaceutical applications. However, in the analysis of biological specimens the hydroxy groups of these steroids are derivatized (mainly acetylated or trimethylsilylated) to avoid irreversible adsorption on the column when trace analyses are carried out. If the aim of the derivatization is to increase the sensitivity, heptafluorobutyrylation and the use of an electron-capture detector are recommended.

It should be mentioned that, with the exception of a few moderately important cases (e.g., GC of estrogen glucuronides after permethylation of both the steroid and the carbohydrate moieties), steroid conjugates (glucuronides or sulfates) are chromatographed as the free steroids after solvolytic or enzymatic hydrolysis.

In the early applications of GC to steroids packed columns were used, but capillary GC has gradually become the standard method in this field. The analyses are usually carried out at temperatures in the range 200–250°C, and hence the thermal stability of the stationary phases, which may be a consideration in some cases, is not problematic. Rather apolar or moderately polar stationary phases of the siloxane

type are most widely used. Fused-silica capillaries, coated with chemically bonded or cross-linked stationary phases, are the most modern separation columns. Relatively few columns are needed to cover all the problems encountered in steroid analysis. For example, a fused-silica capillary 25 m long with an i.d. of 0.2 mm and a layer thickness of 0.33  $\mu\text{m}$  of cross-linked silicone gum (5% diphenyl + 95% dimethyl) can be used to provide an apolar stationary phase. A similar column with a 50% trifluoropropyl + 50% methyl silicone phase can be used to provide a more polar phase. With the aid of two columns such as these, a variety of problems can usually be solved: impurity profiling of steroid drugs, their assay by the internal standard technique, investigation of reaction mixtures, analysis of fermentation liquors, etc.

An important feature of capillary GC is that it is easily combined with MS. The GC-MS technique is not only the most effective method for the identification of the steroid components of complex mixtures (profiling of biological samples, impurity profiling of industrial samples), but various kinds of mass fragmentographic techniques also enable the extremely selective and sensitive quantification of the separated components.

GC-(high resolution)MS after enzymatic hydrolysis of the glucuro- and sulphoconjugates and trimethylsilylation is the most widely used method for the determination of anabolic steroids and their metabolites in the urine of athletes. The most up-to-date technique for the solution of the difficult problem of differentiating between endogenous and exogenous testosterone is gas chromatography – combustion/isotope ratio ( $\text{C}^{13}/\text{C}^{12}$ ) mass spectrometry (GC-C-IRMS).

**Column liquid chromatography (CLC)** In the complex procedures aimed at determining individual steroids in biological samples, CLC plays a predominant role. This technique is mainly used for the separation of steroids from other compounds, for group fractionation of steroids, and for the separation of individual steroids prior to other (usually immunological) assays.

In addition to the classical column packing materials (silica gel, alumina, celite), other widely used columns are of the polydextran gel type: for the fractionation of the polar steroids, Sephadex LH-20, and for the less polar steroid compounds its hydroxyalkyl derivative, Lipidex. The use of ion exchange columns (e.g., DEAE-Sephadex A-25, Amberlite XAD-2) is also widespread. High selectivity is attainable with immunoaffinity chromatography, where antibodies are immobilized on chemically modified agarose gel and filled in columns. For the solid-phase

extraction of steroids from biological fluids  $\text{C}_{18}$ -silica cartridges are most widely used.

**Liquid chromatography** LC was introduced into the analysis of steroid hormones ~10 years after GC. This field of application is now shared by the two techniques, and the advantages and disadvantages of LC must be taken into account when an explanation is sought as to why LC has superseded GC in some areas while GC retained its position in others.

The advantages of LC in steroid hormone analysis are:

1. It is usually carried out at ambient temperature, and for this reason it is applicable quite generally and without derivatization or hydrolysis, even in those cases where thermal instability or low volatility precludes the direct application of GC (separation and quantification of corticosteroids, conjugates, etc.).
2. Although the resolving power of LC is generally lower than that of capillary GC, the greater versatility of LC may be exploited so well that suitable combinations of mobile and stationary phases can be found for the separation of practically all steroids, including 'critical pairs' (epimers, derivatives with various degrees of unsaturation, etc.).
3. LC enables even minor steroid components to be obtained on the semipreparative or preparative scale. This facilitates the identification of metabolites, impurities, and degradation products by subsequent spectroscopic studies.
4. Although coupling the mass spectrometer with the high-performance liquid chromatograph involves greater technical problems than is the case with GC-MS, which is more popular in steroid hormone analysis, LC-MS has already been successfully introduced into steroid profiling. A unique feature of LC is that it can be linked with radioimmunoassay (RIA). The combination of the high resolving power of the former and the high selectivity and sensitivity of the latter produces an extremely powerful method.

Of the various techniques, reversed-phase systems are most frequently used. Their use in biochemical analysis is almost exclusive. It should be mentioned that for the successful determination of the highly polar steroids fully end-capped  $\text{C}_{18}$  columns must be used. Although reversed-phase systems are far more widely used in pharmaceutical steroid analysis, the use of normal-phase systems enables very difficult separation problems to be solved.

Most steroid hormones possess a strong enough UV absorption for sensitive monitoring with the UV detector. For instance, 4-ene-3-oxo steroids can be measured at 240 nm in the nanogram range. This is similar to the sensitivity of the commonly used flame ionization detector in GC. Even the spectrophotometrically inactive steroid hormone derivatives contain weak chromophores (isolated double bonds, oxo groups, etc.), which enable their monitoring in the rather inconvenient short-wavelength range (200–210 nm). The selectivity and sensitivity of detection can be increased by precolumn or postcolumn derivatization. However, derivatization is of only moderate importance in steroid hormone analysis.

An advantageous feature of LC with a diode-array UV detector is that UV spectra are easily obtainable. This is illustrated in **Figures 6A** and **6B** where the diode-array UV spectra of Nestorone and its impurities obtained after reversed-phase LC separation are shown. As seen in **Figure 6B** not only the presence of additional double bond (5) but also an oxo group (4) in conjugation with the chromophoric 4-ene-3-oxo group of Nestorone (1) (see **Table 1**) is of diagnostic value but even the presence of hydroxyl groups at 6 $\alpha$ - (2) or 6 $\beta$ - (3) position causes small but characteristic shift of the absorption maxima.

## Immunoassay Methods

**Introduction** Steroids are not immunogenic, but as haptens covalently bound to a suitable protein they can be used to raise antisera. This is the basis of their determination by immunoanalytical methods. Antibodies raised in this way can more or less selectively bind any steroid, whose protein complex has been used for immunization of the animals producing the antiserum. The competition between the steroid to be determined and a suitably labeled analog forms the basis of immunoassay. In the overwhelming majority of cases polyclonal antibodies are used. The advantage of monoclonal antibodies is their well-defined specificity. A disadvantage, however, is their lower affinity to the antigen, causing difficulties in attaining

high sensitivity. In addition, they are more sensitive to variations in pH and ionic strength.

Depending on the manner of labeling, various kinds of immunoassays are used in the analysis of steroid hormones: RIA, enzyme immunoassay, fluorescence immunoassay, fluorescence polarization immunoassay, and luminescence immunoassay.

While the other quantitative analytical methods for the determination of steroid hormones are more or less generally used for the investigation of both pharmaceutical products and biological samples, the immunoassay methods are used exclusively for biological samples. Although the majority of the problems routinely investigated by these techniques in clinical and biochemical analysis could also be solved by other (mainly chromatographic) methods, immunoassays are the most commonly used methods for the determination of individual steroid hormones in biological samples. The reasons for this are the speed, simplicity, and relatively low cost of these techniques, as well as their high selectivity and extremely high sensitivity. The selectivity of the immunoassay methods can be further increased by preliminary chromatographic separation. Thus, they can serve as extremely sensitive offline detection systems in LC profiling of steroids.

**Radioimmunoassay** For the production of the antiserum, steroids are usually bound to bovine serum albumin (BSA). Usually 10–30 molecules of the steroid per mole of BSA are bound. The easiest binding method is via a hemisuccinate bridge between the 17- or 3-hydroxy groups of the steroid and the lysine moiety of the protein, or the O-carboxymethyloxime bridge between the 3- or 20-oxo group and the lysine moiety of the protein. The selectivity can be increased if the same bridges are built up at other locations in the steroid nucleus where originally no functional group was present. For example, an antiserum for testosterone prepared via the 3-O-carboxymethyloxime has a cross-reactivity of 65% to 5 $\alpha$ -dihydrotestosterone, while this value can be reduced to 0.8% if the 6 $\beta$ -carboxymethyl derivative is linked to the protein.

A variety of tritiated ( $^3\text{H}$ ) steroids are available as the radiolabeled compounds for use in the RIA. The relatively low sensitivity of  $^3\text{H}$  can be increased by multiple labeling. Another alternative is  $^{125}\text{I}$  labeling. Radioiodinated aromatic amines or amino acids, such as tyramine, tyrosine, or histamine, are linked to the steroid by the above-mentioned reactions to obtain the label.

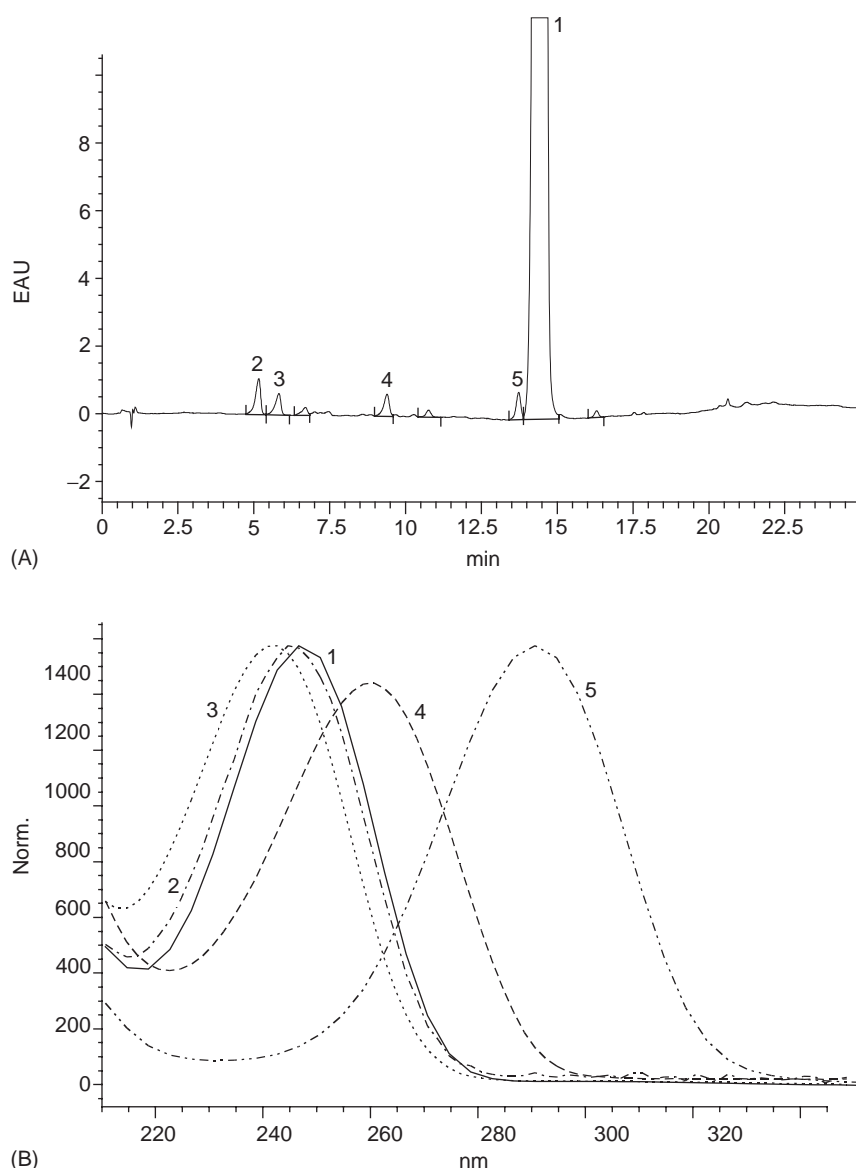

After the equilibration stage of the assay, the separation of the labeled steroid, bound to the antibody from the free steroid, can be achieved in several

ways. The classical, but still widely used method, is the dextran-coated charcoal (DCC) method. Here, the free steroid is adsorbed on DCC, removed by centrifugation, and the radioactivity present in the supernatant is determined by liquid scintillation counting (in the case of  $^3\text{H}$  labeling) or by gamma counting (in the case of  $^{125}\text{I}$  labeling). Other methods based on adsorption and/or precipitation (e.g., with polyethylene glycol) followed by centrifugation are also used in steroid RIAs. In the double-antibody technique, which merits special mention, the steroid bound to the antibody is precipitated by adding a

second antibody. In this case, the free steroid label is measured. Some RIA kits contain magnetizable particles for the bound-free separation.

In the most widely used solid-phase methods no centrifugation step is required. The commercially available kits for steroids contain the antibody (or the second antibody, in the double-antibody technique) immobilized on the walls of a tube, plastic beads, sticks, or membranes.

The sensitivity of the RIA of steroids depends on the affinity of the antibody for the steroid, the background effect of nonspecific binding, the temperature

**Figure 6** LC separation (A) and diode-array UV spectra (B) of Nestorone (1) and its impurities, 6 $\alpha$ -hydroxy (2), 6 $\beta$ -hydroxy (3), 6-oxo (4), 6-ene (5) derivatives. of incubation, and the nature and specific activity of the radiolabel. In typical, optimized methods the calibration graph covers the range 10–1000 pg.

**Enzyme immunoassay** The tendency to avoid the use of radioisotopes in immunoassays has led to the increasing use of nonisotopic labels in steroid hormone assays. Of these, enzyme immunoassays are most widely used.

The coupling of steroids to enzymes is carried out in a manner similar to that described in the previous section for their coupling to BSA. The most frequently used enzymes in steroid assays are horseradish peroxidase and alkaline phosphatase. Although the enzyme activity is conserved in the course of coupling, it decreases during the immunogenic reaction. The enzyme–steroid complex used in the competitive equilibrium may be the same as that used to raise the antiserum (homologous system) or different (heterologous system). The advantage of the former is higher specificity, while that of the latter is improved sensitivity.

Although unlike RIA, enzyme immunoassays can be carried out in homogeneous systems without a separation step (based on the change in enzyme activity during the immune reaction), in practice, heterogeneous (enzyme-linked immunosorbent assay) methods are much more frequently used. The antibody, or in the case of the double-antibody method the second antibody, is immobilized, either covalently or by coating enzyme multiplied immunoassay technique (EMIT). This can be done on the walls of microtiter plates. After the immunogenic reaction, the enzyme activity, which is the equivalent of radioactivity in RIA systems, can be measured by suitable photometric methods on the microtiter plates themselves.

A typical photometric reaction is, for example, the interaction between hydrogen peroxide and 2-phenylenediamine, leading to the colored quinonediimine with an absorption maximum at 492 nm. This reaction is catalyzed by the above-mentioned peroxidase enzyme and, hence, the absorbance is proportional to the concentration of the unbound enzyme steroid complex in the equilibrium mixture.

Generally, the specificities and sensitivities of the enzyme immunoassay methods for steroid hormones are comparable with those of the RIA methods. The sensitivity can be improved by using a fluorophoric reaction to replace the chromophoric reaction. For instance, the horseradish peroxidase discussed above also catalyzes the reaction between hydrogen peroxide and 4-hydroxyphenylacetic acid. The interaction of the oxidation product with glycine leads to a fluorophore (excitation 327 nm, emission 410 nm).

**Other immunoassays** No fluorogenic reaction is needed if the radiolabel or the enzyme label is replaced by a fluorogenic label, which can be measured after the bound-free separation. An example of such a label is 4-methylumbelliferone 3-acetic acid. The advantage of these fluoroimmunoassay methods (FIA) is their simplicity. However, a disadvantage is that, as a consequence of the strong background fluorescence, the sensitivity is poor.

This disadvantage can be overcome by making use of the excellent fluorescence properties of the lanthanide (mainly  $\text{Eu}^{3+}$ ) chelates. These are characterized by high quantum yield, extremely large Stokes' shift (excitation  $\sim 350$  nm, emission  $\sim 610$  nm), narrower emission peaks, and extremely long fluorescent half-life (5–6 orders of magnitude longer than that of the background fluorescence). This enables the two kinds of fluorescence to be separated in the time-resolved fluorimeter, which is widely used in steroid hormone analysis.

The basis of the measurement is that the lanthanide chelate (e.g., isothiocyanatophenyldiethylenetriamine pentaacetic acid- $\text{Eu}^{3+}$ ), conjugated with the antibody, is not fluorescent. In the solid-phase system, after the bound-free separation, effected by simple washing of the walls of the microtiter plates, the above complex of  $\text{Eu}^{3+}$  is caused to dissociate through the action of a stronger complex-forming agent (2-naphthoyltrifluoroacetone), which forms a chelate with the good fluorescence properties listed above. These 'dissociation-enhanced lanthanide fluoroimmunoassay' methods are very popular for the assay of a variety of steroids in biological specimens. In addition to its high sensitivity (comparable to that of RIA), this method is easy to automate.

Other variants of immunoassay methods used in the analysis of steroid hormones are the fluorescence polarization immunoassay, where the label is fluorescein, coupled to the steroid, and luminescence immunoassay, where the steroid is bound to aminoalkylethyl luminol. The basis of the luminescence assay is the luminescence generated by the action of hydrogen peroxide/peroxidase, which is measured by a luminometer (LIA, CELIA).

## Applications

It can be concluded from the outline of the tasks to be solved by steroid analysts and the methods available for these purposes that the gap between the methodologies of industrial/pharmaceutical/regulatory steroid analysis and that of the biological/clinical field is rather wide, and further widening is to be expected in the future as a consequence of the refinement of the methodologies. The main reason

for this is that in the first field the quantity of the sample available for the analysis is practically unlimited, the number of components is usually low, and matrix effects are easy to handle. For these reasons, sensitivity is not a major problem and the demands regarding specificity are also few. On this basis, UV spectrophotometric and colorimetric methods still play an important role and GC as well as LC (the most widely used technique in industrial/pharmaceutical/regulatory steroid analysis) can be used with their conventional detectors.

At the same time, in biological/clinical steroid analysis where extremely low concentrations of steroids (and at an increasing rate their individual conjugates) have to be determined in the presence of several structurally closely related derivatives and in complicated matrices, both the sensitivity and the selectivity of the methods are of great importance, but the demands regarding the accuracy and precision of the methods are naturally lower than in the other fields. For this reason immunological methods are most widespread either directly or after chromatographic separation. The use of colorimetry and fluorimetry is becoming restricted to various kinds of enzyme- and fluoroimmunoassays where these labels and reactions serve as the basis of the quantitative evaluation. GC plays an important role in this field too, mainly in conjunction with MS. This is not only a tool for the identification of steroids but also a reference method for their quantification in clinical samples. This is the predominant method in the doping analysis of athletes. The importance of LC-MS, too, has greatly increased due to the use of the new ionization techniques in mass spectrometry.

# HUMIC AND FULVIC COMPOUNDS

**M Filella, J Buffle, and N Parthasarathy**, University of Geneva, Geneva, Switzerland

## Introduction

Humic substances refer to products resulting from the decomposition of plant and animal residues. They are omnipresent in soils, sediments, and water.

They constitute  $\sim 75\%$  w/w of the organic matter in most soils and  $\sim 50\%$  of the organic carbon in surface waters. Humic substances are composed of complex heterogeneous mixtures of organic compounds and are characterized as being yellow to brown in color, of high relative molecular mass, and refractory. Unlike many other natural organic products, they cannot be described in terms of unique chemical structures and are operationally defined by the technique used for their extraction and fractionation.

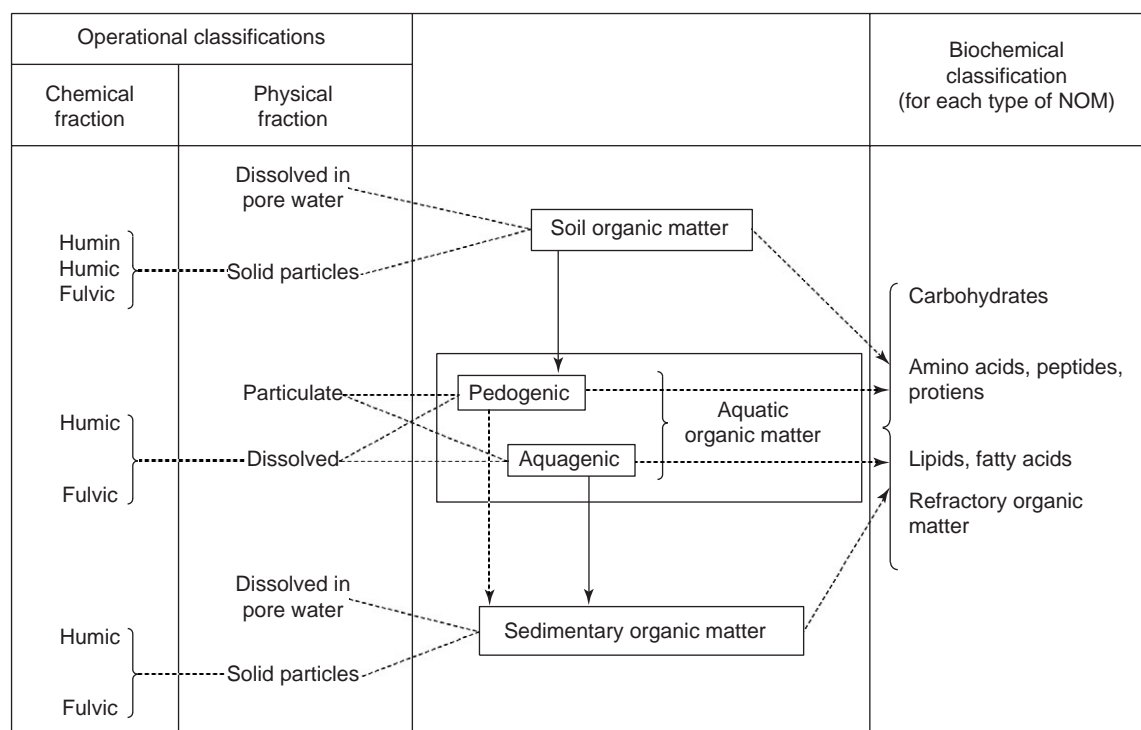

Soil humic substances have been studied since the eighteenth century because they are essential for holding water and nutrients and releasing it to plants. In recent years, the importance of humic substances in aquatic systems, especially in water quality, was realized and aquatic humic substances have been investigated by scientists in aquatic chemistry and limnology. The presence of these substances in natural water systems affects markedly the productivity of plant systems, influences the distribution of many other organic and chemical species in the environment, and produces toxic by-products when exposed to water disinfectants containing halogen.

## Definition and Classification

Natural organic matter (NOM), other than living organisms and anthropogenic compounds, possesses

a large variety of properties and is composed of an extremely complex mixture of compounds, most of which are not yet identified. Taking into account the diversity of the natural processes of synthesis and degradation, the number of constituents in this mixture can be considered as infinite and therefore there is little hope of completely separating them. Consequently, studies of NOM have nearly always been concerned not with pure compounds but rather with groups of compounds separated from the initial mixture by means of relatively arbitrary chosen techniques.

Figure 1 shows the classification of various types of NOM. The biochemical classification is the best justified from a theoretical perspective. It distinguishes between the three major classical groups: carbohydrates, proteins, and lipids. In water, these together represent only  $\sim 20\text{--}30\%$  of the NOM, the remaining components being materials resistant to degradation (refractory organic matter). The physical size classification serves to distinguish between particulate and dissolved NOM. The boundary is defined in a purely operational and arbitrary way, usually by use of  $0.45\text{ }\mu\text{m}$  pore filters. The chemical fractionation classification yields fractions that may include mixtures, in varying proportions, of the 'biochemical' compound mentioned above. The most widely used fractionation is separation into fulvic and humic compounds. Humic compounds are the fraction that

**Figure 1** Classification of various types of NOM. (From Buffle J (1984) Natural organic matter and metal-organic interactions in aquatic systems. In: Sigel H (ed.) *Metal Ions in Biological Systems*, p. 165. New York: Dekker.)

is soluble at alkaline pH but precipitates at acidic pH, and fulvic compounds the fraction water soluble at alkaline and acidic pH. The terms humic and fulvic compounds imply only specific acid–base solubility behavior, and these organic fractions isolated from diverse environments do not necessarily have similar chemical structures or result from similar source materials or formation processes.

The environment clearly influences humic substance formation not only by dictating the range of possible precursors but by influencing the type of possible processes. Thus, the principal source of seawater NOM is planktonic and bacterial excretion and degradation while, in contrast, terrestrial biomass and NOM production is principally provided by higher plants. A major problem in elucidating environmental influences is that humic substances are often isolated from different environments than those in which they were formed. For example, of all aquatic systems, lakes present one of the most complex mixtures of NOM because they accumulate in a limited space organic matter from several different sources: primary autochthonous productivity of the same type as that of oceanic pelagic zones, allochthonous inputs, and the release of sediment organic matter. A classification of humic materials based on the origin of the compounds (aquagenic, pedogenic (Figure 1)) would probably be more environmentally sound than the current separation schemes based on pure analytical considerations.

## Isolation and Fractionation

Humic acids do not occur alone in the environment. They occur in mixtures with amino acids, sugars, various aromatic and aliphatic acids, and other organic compounds, and/or associated with mineral components. In order to study the chemistry of humic substances, they must be first isolated. Because humic and fulvic acids are defined by the technique that is used for their extraction, and in order to get comparable results, it is particularly recommended to follow the isolation procedures used by the International Humic Substance Society (IHSS).

### Isolation from Soils

The classical method for isolation of humic substances from solid-phase source materials such as soils, peat, and leonardite is alkaline extraction with aqueous NaOH, followed by precipitation of humic acid at low pH, and a series of desalting steps involving cation exchange, dialysis, etc., to obtain fulvic acid. Through this procedure, samples extracted from solid-phase materials include both

hydrophobic and hydrophilic acids. A number of methods for the extraction of humic substances from soil using sodium hydroxide solution have been published. These methods are generally successful and yield comparable results. The one described below is the method currently used by the IHSS. It produces relatively high yields and can be used as a standard method for comparisons between and within laboratories.

After removing roots and sieving the dried soil sample to pass a 2.0 mm sieve, the sample is equilibrated at a pH value between 1 and 2 with HCl (final ratio 10 ml liquid–1 g dry sample). The supernatant is kept for the isolation of the fulvic acid. The soil sample is first neutralized to pH 7 with  $1 \text{ mol l}^{-1}$  NaOH then  $0.1 \text{ mol l}^{-1}$  NaOH is added under  $\text{N}_2$  atmosphere to give a final extractant-to-soil ratio of 10:1. After extraction and settling for some hours, the alkaline supernatant is collected and acidified with  $6 \text{ mol l}^{-1}$  HCl to pH 1. After standing for 10–12 h, centrifugation allows the separation of the humic acid (precipitate) from the fulvic acid (supernatant). The two supernatants containing the fulvic acid fraction are purified by using a XAD-8 resin. They are finally  $\text{H}^+$ -saturated by using a cation-exchange resin and freeze-dried. The humic acid fraction is redissolved by adding KOH under  $\text{N}_2$  and purified by repeated precipitation, treatment with HCl and HF, and dialysis. Humic acids are freeze-dried.

XAD-8 is a nonionic, macroporous (pore size  $25 \mu\text{m}$ ), methyl methacrylate ester resin. Because it is sometimes difficult to obtain, it may be necessary to use an alternative resin such as Polyclar, which is a cross-linked poly(vinylpyrrolidone). Extensive purification of the resins is always required before use.

If it is not possible to purify the fulvic acid using resin treatments, exhaustive dialysis against distilled water is an alternative method. However, it is less convenient because much of fulvic acid has proved to pass through commercially available dialysis membranes.

### Isolation from Water

Humic substances can be isolated from waters by using column adsorption techniques and concentrated by methods such as vacuum distillation, lyophilization, freezing concentration, ultrafiltration, reverse osmosis. The IHSS has adopted the XAD-8 resin adsorption method to isolate humic and fulvic acids from natural waters. In this method, after filtration through a  $0.45 \mu\text{m}$  silver or polymer membrane filter, the dissolved organic matter (DOM) is fractionated initially into hydrophobic and hydrophilic fractions through preferential adsorption of the hydrophobic fraction on the XAD-8 resin (water sample preacidified at pH 2

with HCl). Subsequently, the hydrophobic fraction is eluted from the resin by alkaline extraction with aqueous  $0.1 \text{ mol l}^{-1}$  NaOH, followed by precipitation of humic acid at low pH (pH 1, adjusted with HCl), and a desalting step involving cation exchange to obtain fulvic acid. Finally, fulvic and humic acids are freeze-dried. The humic acid and fulvic acid that are isolated from aqueous samples thus contain only hydrophobic organic acids. Starting in the late 1990s, IHSS has also employed reverse osmosis to concentrate NOM from selected water sources.

Standard and reference samples of humic substances (river, soil, peat, leonardite) are available from the IHSS. They can be used for quality control of analytical work on humic substances.

### Characterization: Physical Properties

Any isolate of soil and water humic substances is intrinsically polydisperse, and physical and chemical properties derived from these substances are average values (Figure 2). In some cases, it is preferable to

determine distribution curves (or spectra) that relate the changes in the population of the distribution to the value of the parameters used (e.g., number of particles versus particle size, number of complexing sites versus their complexation stability constants). When this approach is not taken, the polydispersity of the system should be addressed in order to guide the average values estimation.

### Charge

Humic substances invariably carry an electrostatic charge. They are therefore classified as polyelectrolytes. Although a variety of sites possessing the potential to carry a positive or negative charge can be identified on humic substances, the predominant charge is negative and at most naturally occurring pH values this charge is due to the dissociation of carboxylic, hydroxyl, and phenolic groups. Typically, soil humic acids have 3–4 charge types per 1000 Da, which is a relatively high level for a naturally occurring polyelectrolyte. The presence of

**Figure 2** Proposed model chemical structure for fulvic compounds. (Reproduced with permission from Schulten H-R and Schnitzer M (1993) *Naturwissenschaften* 80: 29–30.)

electric charge and of the necessary counterbalancing ions has a marked effect on any measurement of relative molecular mass, shape, or size in solution, as well as on the metal complexation properties of these substances. A typical example of this effect is exhibited when charge of the humic substances in soil samples is determined by *in situ* and laboratory measurements. The total acidity of the *in situ* soil organic matter is much lower than that of soil extracted humic and fulvic acids. This is probably due to the potential charge site being blocked by interaction with other soil components.

### Degree of Hydration

The degree of hydration of humic compounds is high. It can be estimated from the hydration number of the hydrophilic groups and from the composition of humic and fulvic acids. Calculations show that at least 0.8 and 0.9–1.5 g of water are retained per gram of soil humic acid and soil fulvic acid, respectively. A similar value for the degree of hydration has been found for dissolved water fulvic acid. Hydrogen-bridge formation is probably the basis for hydration of both fulvic and humic acids.

### Relative Molecular Mass, Size, and Shape

Numerous methods have been applied for the determination of the relative molecular mass, size, and shape of humic and fulvic acids: colligative properties measurements (vapor pressure osmometry, cryoscopy), viscometry, exclusion (gel) chromatography, field flow fractionation, ultracentrifugation, ultrafiltration, small-angle X-ray scattering, light scattering, electrophoresis, fluorescence correlation spectroscopy, transmission electron microscopy (TEM) (Figure 3), and atomic force microscopy (AFM) (Figure 4). Size determinations depend on the polydispersity and polyelectrolytic nature (charge effects) of the compounds as well as on their aggregation and hydration properties. Consequently, the results in the literature are relatively disparate. Data on the molecular radii of humic substances vary from fractions of nanometers to several hundreds of nanometers. In general, the aggregation phenomena can be minimized by using the lowest possible concentrations of organic matter and electrolytes and media not too acidic.

As a result of polydispersity of the compounds, the measured relative molecular masses are weighted averages of the relative molecular masses of all the individual components. Depending on the method used, the weighting can be based on the number of molecules containing the sample (osmotic pressure, vapor pressure osmometry, depression of freezing point), on their weight proportion with respect to the

**Figure 3** Transmission electron micrographs of a water fulvic acid; spheres (minimum visible size 2–3 nm) and spheroidal aggregates. Scale bar = 450 nm. (Reprinted with permission from Leppard GG, Buffle J, and Baudat R (1986) *Water Research* 20: 185–186; © Elsevier.)

total mass of the compounds (sedimentation velocity, light scattering), or on the  $z$ -value (ultracentrifugation). The differences among these values increase with polydispersity.

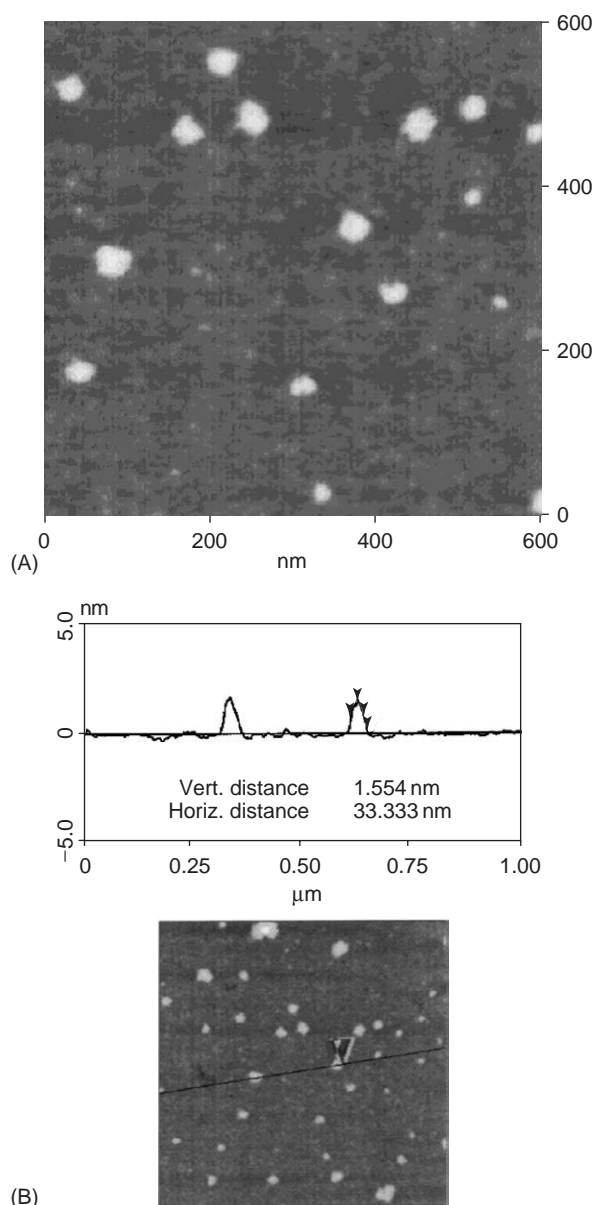

Humic acid colloids are mass fractals in aqueous solution. Their fractal dimension varies as a function of metal content, organic functional group content, and the separation technique applied in the original extractions. The range of fractal dimensions found – from 1.3 to 2.8 – suggests that their formation processes extend beyond usual aggregation descriptions (diffusion limited, reaction limited aggregation regimes).

## Characterization: Chemical Composition and Structure

### Elemental Analysis

Elemental analysis includes carbon, hydrogen, oxygen, nitrogen, phosphorus, sulfur, halogen, and elemental ratios C/H, O/C, and C/N. Typical elemental composition of water and soil humic substances are shown in Table 1. Carbon is the major element and it

**Figure 4** (A) AFM image of isolated Suwannee River humic acid macromolecules ( $10 \text{ mg l}^{-1}$ ;  $50 \text{ mmol l}^{-1}$  NaCl, pH 5.5) adsorbed on mica. Scan size is  $600 \text{ nm} \times 600 \text{ nm}$ . (B) Cross-sectional analysis of the image shown at the right-hand side. The height of the measured particles is  $1.6 \text{ nm}$ , and the lateral dimension at half-height (overestimated) is  $33 \text{ nm}$ . (Reprinted with permission from Balnois E, Wilkinson KJ, Lead JR, and Buffle J (1999) *Environmental Science and Technology* 33: 3911–3917; © American Chemical Society.)

varies between 50% and 60% for humic acids and between 40% and 50% for fulvic acids. There are very little differences in H, N, and S contents. The ash content of humic substances depends on the isolation procedure. Ash contents of less than 1% are found if the XAD resin method is used for isolation.

### Isotopic Ratio

The isotopic ratio provides information on the origin of humic substances. During biochemical and chemical reactions, the isotopes of a given element undergo fractionation, which depends not only on their mass, but also on the nature of the reaction. Isotopic ratios, in particular those of  $^{13}\text{C}/^{12}\text{C}$ , depend on the organic matter evolution and enable the origin of the organic matter to be specified to some degree. The humic substances (primarily as fulvic acids) in deep ocean waters have been established to be 3000–6000 years BP with a  $\delta^{13}\text{C}$  of  $-22$  to  $-23$  ppm. All stream humic substances analyzed to date have  $^{14}\text{C}$  ages near zero (all modern carbon) with  $\delta^{13}\text{C}$  values between  $-25$  and  $-28$  ppm. The  $^{14}\text{C}$  and  $\delta^{13}\text{C}$  values for soil humic substances vary considerably. The  $^{14}\text{C}$  age of humic acids in soils varies from a few hundred years to several thousand years;  $\delta^{13}\text{C}$  values range from  $-25$  to  $-31$  ppm. Such range for soils may reflect cropping practices and residue management, the methods used for isolation of fulvic and humic acids and sampling techniques rather than true pedogenic differences.

### Functional Groups

Table 1 shows the functional groups in water and soil humic and fulvic fractions. The major functional groups are carboxyl, phenolic hydroxyl, hydroxyl, and carbonyl. The sum of carboxyl and phenolic hydroxyl is total acidity. Total acidity of water fulvic acids is slightly higher compared to soil fulvic acids while total acidity of soil and water humic acids is comparable.

Carboxyl group content is determined either by potentiometric titration of humic material or by calcium acetate titration. Calcium acetate method overestimates carboxyl content by at least 10%. Potentiometric titration of humic substances (pH 2.8) in  $0.1 \text{ mol l}^{-1}$  KCl with a base up to pH 10 yields more precise values for carboxyl content.  $^{13}\text{C}$  nuclear magnetic resonance (NMR) (solid and liquid) can also be used for carboxyl determination. The results obtained are comparable to potentiometric titration.

Phenolic hydroxyl content is more difficult to determine by potentiometric titration owing to the weak acidic nature of phenolic hydroxyl. Phenolic hydroxyl content can, therefore, be only estimated. Again  $^{13}\text{C}$  NMR can be used for estimation of phenolic hydroxyl content. Comparable values are obtained using both these methods, e.g.,  $1\text{--}2 \text{ meq g}^{-1}$  for water humic substances. This is less than phenolic hydroxyl content of soil humic substances, which is  $3.0\text{--}3.9 \text{ meq g}^{-1}$ . Phenolic contents of water humic

**Table 1** Composition of soil and water humic and fulvic acids

<i>Parameter</i>	<i>Soil humic acid</i>	<i>Water humic acid</i>	<i>Soil fulvic acid</i>	<i>Water fulvic acid</i>
<i>Elemental composition (%)</i>				
C	53.8–58.7	53.4–59.4	40.7–53.1	41.6–51.1

Aliphatic COOH	9			15
Aromatic COOH	20			24
Phenolic OH	14			12
(aliphatic + carbohydrates OH)	57			49

substances are considerably less than soil humic substances. This is an important difference between soil and aquatic humus.

### Analysis of the Chemical Structure

The methods that have been used for obtaining information on the chemical structure can be divided into two groups, viz., degradative and nondegradative methods.

**Degradative methods** Degradative methods include oxidative and reductive degradation, hydrolysis, various types of irradiations, pyrolysis, biological degradation. The oxidative degradation method is one of the most useful methods for obtaining information on chemical structure. Several reagents have been used for oxidation of humic substances: under alkaline conditions, potassium permanganate, copper(II) oxide, aqueous chlorine; under acidic conditions, nitric acid, peracetic acid, hydrogen peroxide; and ultraviolet (UV) radiation. Alkaline permanganate oxidation seems to be the best method, from the standpoints of producing relatively large amounts of identifiable digest products and providing significant information on the chemical

structures of humic substances. Premethylation is important for obtaining good yields. In all oxidative degradations, soil substances essentially produce carboxylic acids (mono-, di-, tri-, and tetra-), phenolic acids, and benzenecarboxylic acids. There are indications that whereas soil humic acids and soil fulvic acids yield similar quantities of aliphatic compounds on oxidation, the oxidation of soil fulvic acids yields more phenolic acids but fewer benzenecarboxylic acids than does that of soil humic acids.

The most widely used reductive degradation methods are zinc distillation and sodium amalgam reduction. Fused aromatic structures (methyl substituted naphthalene, anthracene, pyrene, and perylene) are the major digest products of this reduction of humic substances.

Nowadays, analytical pyrolysis is widely used. Recently, there have been significant improvements in the pyrolysis procedure and, by coupling pyrolysis to gas chromatography (GC) and mass spectrometry (MS) a significant body of structural information on humic substances may be obtained. However, quantitation of pyrolysis GC–MS is limited by matrix effects that distorts the signals of detected and the high temperatures used during pyrolysis produce

secondary reactions (rearrangement, cracking, hydrogenation, and polymerization). Therefore conclusions regarding structural make-up of the original samples must be drawn with caution. Another modern method is thermo-chemo analysis with tetramethyl ammonium hydroxide coupled to mass spectrometry. Its advantage is that numerous polar functionalities associated with humic substances, which are not detected by other methods, can be detected, e.g., propyl side-chains.

In the last decade there has been a fast progress in the field of mass spectrometry employing soft ionization techniques such as electrospray ionization mass spectrometry (ESI-MS), Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR-MS), and matrix-assisted laser desorption ionization mass spectrometry (MALDI)-MS. These tools provide molecular level information on humic substances.

**Nondegradative methods** The nondegradative methods used for obtaining information on chemical structure and properties include infrared (IR) and UV-visible spectroscopy, spectrofluorimetry, electron spin resonance (ESR) spectroscopy, and NMR. The study of humic substances is the study of complicated, ill-defined mixtures. Most of the physical and chemical methods of investigation are confined to simple systems and the analyst's ability to interpret the data is extremely limited. In applying any spectroscopic method to humic substances, measurement is taken of the summation of the signals of the numerous components in the mixture that respond to that particular frequency range, with all signals superimposed upon each other. What is measured is the net or average response of these particular components in the assemblage. Therefore, in the case of humic substances, there is little point in seeking definite structure but instead have a knowledge of the types of structures in the mixtures and the types of association structure that these can form.

**Infrared spectroscopy** IR and Fourier transform infrared (FTIR) spectra of humic substances show bands at  $3400\text{ cm}^{-1}$  (H bonding OH),  $2990\text{ cm}^{-1}$  (aliphatic C-H),  $1725\text{ cm}^{-1}$  (C=O of  $\text{CO}_2\text{H}$ , C=O of ketone),  $1630\text{ cm}^{-1}$  (aromatic C=C, C=O of carbonyl,  $\text{COO}^-$  or quinone),  $1450\text{ cm}^{-1}$  (aliphatic C-H),  $1400\text{ cm}^{-1}$  ( $\text{COO}^-$ ) and  $1200\text{ cm}^{-1}$  (C-O or OH of  $\text{CO}_2\text{H}$ ). The bands are usually broad due to overlapping of individual absorbances. While IR and FTIR provide worthwhile information about functional groups, they reveal little about the chemical structure of humic substances. FTIR and diffuse reflectance infrared Fourier transform (DRIFT) are the techniques most widely used.

**Ultraviolet-visible spectroscopy** UV-visible spectra of humic substances are generally featureless. The technique has little value for studying functionality of humic substances and cannot be used for the direct determination of functional groups in these materials. Nevertheless, UV-visible spectroscopy does have other useful applications such as the estimation of the degree of humification using  $E4/E6$  ratios (the ratio of the absorbance at 465 nm to that at 665 nm) and for determining the concentration of dissolved humic substances based on Beer's law plots. The ratio UV absorption at 280 nm/dissolved organic carbon (DOC) allows to estimate the contribution of the two major groups of dissolved NOM (pedogenic versus aquagenic, see Figure 1) on the basis of their chemical structure.

**Spectrofluorimetry** Fluorescence measurements of humic substances can provide criteria for the differentiation and classification of substances of various origins. Humic substance groups are excited at  $\sim 350\text{ nm}$  and emit at  $\sim 450\text{ nm}$ , a spectral region relatively free from interference by other groups. Measurement of the fluorescence is a relatively selective method of analysis. Fluorescence cannot be used for the direct determination of functionality.

**Electron spin resonance spectroscopy** The ESR spectrum of humic and fulvic acids consists of a single line identified by its position and width. In general, the ESR spectra are devoid of hyperfine splitting. The ESR spectra of humic substances result from only a small fraction of the total number of molecules that comprise the humic and fulvic acids. The number of free radicals per unit weight, the  $g$  value and the line width can be calculated. The predominant radicals are semiquinones. Comparison of the ESR properties among humic fractions reveals that fulvic acids contain greater quantities of free radicals than humic acids.

**Nuclear magnetic resonance spectroscopy** Nuclear magnetic resonance spectroscopy has made a significant contribution to our knowledge of the structure of humic substances. Samples can be analyzed either by solid state or liquid state NMR. Typical  $^{13}\text{C}$  NMR spectra of solid state and liquid state of soil humic substances show that chemical shifts are mostly the same for liquid and solid state. The most popular  $^{13}\text{C}$  NMR technique for the study of humic materials and coal is the combination of cross-polarization (CP) and magic angle spinning (MAS) on solids. Scores of papers have been published on the application of CP-MAS  $^{13}\text{C}$  NMR to the study of humic samples these last years. The advantages of the solid state over the liquid state is that there is no concentration

limit and no solubility concerns, the solid state is more stable over time than solutions, and there is less sample handling involved. The CP-MAS technique also has the advantage of giving better signal in less accumulation time. It is now possible to obtain good relaxation parameters for humic materials within a reasonable spectral acquisition time (2–4 days). However, evidence has grown that indicated that a substantial fraction of the carbon content indicated by classic elemental analysis is missed in some samples by CP-MAS  $^{13}\text{C}$  methods. Typical CP-MAS  $^{13}\text{C}$  NMR spectra of Laurentian humic and fulvic acids are shown in Figure 5. Table 2 shows the corresponding chemical shift assignments.

**Figure 5** Ramp-CP-MAS  $^{13}\text{C}$  NMR spectra of Laurentian fulvic acid (top) and humic acid (bottom). (Reprinted with permission from Cook RL and Langford CH (1998) *Environmental Science and Technology* 32: 719–725; © American Chemical Society.)

Recently, liquid and solid state  $^{15}\text{N}$  NMR has become a powerful tool for determination of chemical structure of humic substances. The  $^{15}\text{N}$  NMR spectra of humic substances show evidences of the presence of quinones, ketones, and esters. Also it shows that most of the nitrogen occurs in amide forms.

Newly developing multidimensional NMR might become a powerful tool in the future for obtaining valuable information on the chemical structure of humic substances. Two-dimensional phase-sensitive  $^{13}\text{C}$ ,  $^1\text{H}$  correlation spectra has also been successfully applied for substructure elucidation in size-fractionated humic substances.

## Complexation Properties

The evaluation of interactions between trace metals and humic substances has received considerable attention. Evidence for strong complexation has been demonstrated under controlled experimental conditions. However, the complexity of fulvic and humic compounds is often at odds with the amount of information contained in the experimental data, thus making it very difficult to obtain a rigorous thermodynamic description of their complexing properties.

When the complexation reaction is studied by titration with a metal ion, the concentration of the free metal ion is monitored typically by an electrochemical method, such as potentiometry with an ion-selective electrode, differential pulse polarography, or anodic stripping voltammetry. Fluorescence spectroscopy is being increasingly used to study the reaction of humic material with paramagnetic metal

**Table 2** NMR chemical shifts of Laurentian fulvic acid (top) and humic acid (bottom)

Chemical shift assignments	Chemical shift regions (ppm)	% TOC	$T_{1\rho}$ $^1\text{H}$ (ms)	$T_2$ $^{13}\text{C}$ (ms)

ions that quench the fluorescence of humic matter. Indirect methods based on differences in size such as equilibrium dialysis, ultrafiltration, and size exclusion (gel) chromatography have also been applied. Some of the main experimental difficulties encountered are:

1. Determination of the molar concentration of total complexing sites. The molar complexation of total complexing sites is most often not measurable unambiguously because the relative molecular mass of the complexing entity is generally not clearly defined. A surrogate concentration expressed, for example, in grams of carbon per liter must be used.
2. Limited analytical window. The analytical windows of the different techniques available are smaller than that required to 'cover' all the complexing sites of a humic substance. Moreover, average equilibrium constants calculated by using different techniques will give noncomparable values.
3. Data need to be collected under conditions of metal concentration as close as possible to those existing in natural environments. Use of unrealistic high metal loading conditions and extrapolations of the results so obtained to natural conditions cannot give realistic complexation data.

Humic and fulvic compounds exhibit a wide range of free energy for metal complexation since they possess two major characteristic properties: (1) polyfunctionality: each molecule possesses many complexing sites of different chemical nature; (2) polyelectrolytic nature: all complexant molecules bear high electric charge densities due to the presence of a large number of dissociable functional groups per physical entity. Complexation properties have been represented by means of average parameters, usually one or more site concentrations and stability 'constant' couples corresponding to one or more site types, but the use of such average parameters should be avoided. They have no physicochemical meaning since (1) they are not constant over the entire titration as the free metal ion concentration is successively controlled by sites of different nature and (2) the measured values depend on the analytical window of the method used. They represent only average equilibrium quotients or overall site concentrations for a range of site types having widely different affinities. More sophisticated interpretation methods have been developed, e.g., application of semiempirical complexation isotherms or *a priori* affinity spectra. All these methods have in common a conceptual approach similar to that used in the study of metal complexation by simple ligands: a number

of assumptions are made concerning the nature of the reactions taking place followed by the fitting of the resulting mathematical model to the experimental data. For major sites such a 'classical' description of the complexing behavior may be applicable, provided the necessary corrections to take into account the influence of physical factors such as changes in electric charge density or particle conformation are made, but for minor sites, the complexity of humic compounds is much too great to be unambiguously represented by any model based on *a priori* assumptions that include all the necessary descriptive parameters. In order to overcome these difficulties, two interpretation models that tend to minimize the imposition of *a priori* assumptions have been proposed: the site affinity distribution function and the differential equilibrium function. None of these models is entirely satisfactory, but the conceptual approach that is embodied in them is definitely more consistent with the complexity of humic substances.

Interpretation of binding by noncompletely labile systems, such as it is often the case with humic and fulvic compounds, and assessment of their relationship to biogeochemical processes require combined equilibrium and kinetic approaches. In some cases, kinetics may even predominate over equilibrium considerations. The importance of kinetic studies is increasingly being realized and within the past few years many studies have been reported. Techniques employed include fluorescence quenching, ligand exchange with simple complexants, thermal lens spectrometry, isotope exchange, complexing resins, ion-exchange resins, and ion exchange coupled with voltammetric detection. Site heterogeneity will influence both the equilibrium and kinetic properties of the complexes.

### Introduction

Immunoassays are analytical methods that achieve the detection and quantitation of analytes in biological or environmental samples through the formation of a stable complex between the analyte and a specific antibody. By labeling the analyte or the antibody, or another constituent of the assay, complex formation results in a measurable change in the distribution and/or activity of the label, allowing very

sensitive measurements to be obtained. Immunoassays are simple, rapid, inexpensive, and versatile, and they are very amenable to automation and multiplexing. Therefore, they play an important role in many technological areas, including analytical chemistry, pharmacology, molecular cell biology, and clinical biochemistry. They have become standard practice in many laboratories around the world, and a large number of companies market diagnostic or detection kits that use immunoassays to measure the levels of particular analytes of interest, such as pollutants, hormones, disease markers, and pathogens. In the last few years, both solution-phase and solid-phase immunoassays have become increasingly sensitive and sophisticated, culminating in the development of biochips with arrayed antibody microdots that can be used for the highly multiplexed analysis of hundreds or even thousands of individual analytes

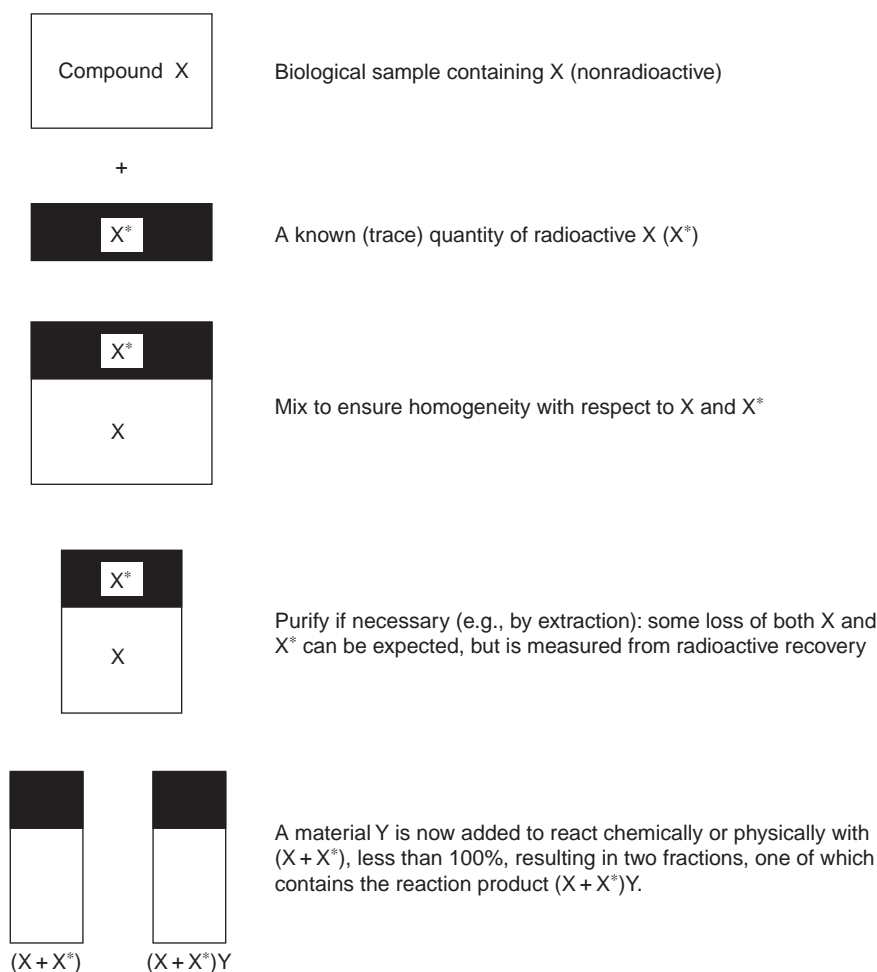

in a complex sample. This article presents a general overview of the principles of the immunoassay and describes some of the more widely used variations of the technique. Subsequent articles deal with methods for the production of antibodies, and specific applications.

## Radioimmunoassays

The first immunoassay technique was the isotopic dilution radioimmunoassay, developed by Rosalyn Yalow and Solomon Berson for the detection of insulin in human blood. This work gained Yalow a share of the 1977 Nobel Prize for Physiology and Medicine, but Berson was not honored because of Nobel rules stating that the prize cannot be awarded posthumously. The following passage, translated from the presentation speech, explains the technique in simple terms: "...As a result of mixing in a test tube a known quantity of radioactive insulin with a known quantity of antibodies against insulin, a

specific amount of the insulin becomes attached to these antibodies. Subsequently, if one adds to this mixture a small amount of blood which contains insulin, the insulin from the blood becomes similarly attached to the antibodies and a certain portion of the radioactive insulin is detached from the antibodies. The higher the concentration of insulin is in the blood sample, the larger is the amount of radioactive insulin that will be detached from the antibodies. The amount of radioactive insulin thus removed can easily be determined, providing an exact measure of the amount of insulin present in the blood sample..."

The isotopic dilution radioimmunoassay is based on the principle of saturation analysis, which is outlined in **Figure 1**. A test compound (in this case insulin, represented by X) is quantified by its ability to progressively saturate a suitable reagent (in this case an antibody specific for insulin, represented by Y). In the first step, a known quantity of radioactively labeled tracer insulin ( $X^*$ ) is added to the sample,

**Figure 1** Principles of saturation analysis. Y is typically an antibody or other protein, or charcoal; it alters the properties of X. The proportional distribution indicates the extent of reaction between X and Y, which is related to X in standards and samples.

which increases the total amount of insulin to  $(X + X^*)$ . Antibody Y is then added to the sample. The amount of Y added must be lower, in molar terms, than  $(X + X^*)$  so that the analyte and tracer are not saturated, and can compete for a limited number of Y sites. Also, it must be possible to separate  $(X + X^*)$  from  $(XY + X^*Y)$ , so that the extent of the complex formation can be determined by the proportional change in the distribution of radioactivity between  $(X + X^*)$  and  $(XY + X^*Y)$  at the beginning and end of the assay. Thus, the first radioimmunoassays were often classified according to how this separation was achieved (e.g., using polyethylene glycol or a second antibody) and were generally referred to as heterogeneous assays because separation into two phases was necessary. In general terms, the more analyte X present in the sample, the more  $X^*$  would be displaced from Y and the more of the radioactive label would remain in the unbound fraction  $(X + X^*)$ . A calibration graph is required, showing the distribution of radioactivity against known quantities of X in standards, allowing unknown quantities of X in experimental samples to be assessed in terms of the distribution of radioactivity.

In the above immunoassay format, the analyte is the labeled entity and the assay is carried out in solution. The principle is similar to that of the competitive protein binding assay, which has been used for many years to characterize receptor–ligand and enzyme–substrate interactions. The intrinsic advantages of the radioimmunoassay over other forms of competitive assay are the specificity of the antibody–analyte interaction and the general applicability of antibodies as opposed to other interacting reagents. Antibodies can be raised against any immunogenic molecule, and even small molecules that do not induce an immune response can be attached to carrier molecules as haptens to render them immunogenic. However, the necessity to label the analyte in each type of experiment and the need to use infinitesimally small concentrations of reagents often causes technical problems and it is impossible to measure more than one analyte simultaneously.

The next significant development was the immunoradiometric assay (IRMA), in which the isotopic label is attached to the antibody rather than the analyte, thus resolving problems associated with labeling diverse analytes. This was the first example of a sandwich immunoassay, in which two antibodies are used firstly to capture the analyte and then to detect and quantify it. It was also the first example of a solid-phase heterogeneous immunoassay, i.e., the first (capture) antibody is immobilized on a solid substrate such as the surface of a microtiter dish or membrane. The surface is then flooded with the

sample, resulting in the capture of the analyte and the formation of antibody–analyte complexes. After washing to remove unbound components of the sample, the surface is flooded with a probe antibody labeled, e.g., with  $^{125}\text{I}$ . A further washing step then removes the unbound probe antibody and the surface is dried and exposed to a film or placed in a gamma counter. Control samples spiked with different amounts of the analyte can be used to produce a calibration graph, allowing the concentration of the analyte in the experimental sample to be determined.

The great advantage of this method is that quantitative data are generated by measuring a stoichiometric interaction between labeled antibody (present in excess) and the captured analyte. The signal produced by the antibody is thus directly proportional to the concentration of the analyte, rather than being related to it in a complex manner as is the case for competition analysis. The limitation of this method is that two antibodies recognizing different epitopes on the target analyte are required. Therefore, while it is suitable for the detection of large molecules such as proteins, it cannot be used to detect small organic molecules, which often fit completely within the antigen-binding pocket of the antibody.

## Nonisotopic Immunoassays

Radioisotopes are convenient labels with high specific activity, and they continue to be used in many laboratories. However, due to potential health hazards, the expense of radioisotopes and the apparatus used to detect them, the short half-life of  $^{125}\text{I}$ , and issues surrounding the storage and disposal of low-level radioactive waste, there has been considerable interest in alternative labeling strategies. Another significant development in the history of immunoassays is therefore the increased use of nonisotopic labels, which include enzymes that catalyze colorimetric or chemiluminescent reactions, and fluorogenic compounds. Many of these labels incorporate intrinsic amplification strategies to increase signal intensities, or can be coupled to systems that provide extraneous signal amplification. Some of these immunoassay formats are discussed in more detail below.

### Homogeneous Competition Assays with Nonisotopic Labels

Although radioactive labels are unaffected by antibody–analyte interactions, the performance of other types of labels can be made to depend on either the formation or disruption of such a complex. This removes the necessity to separate the bound and unbound fractions in competition assays since the label

would only be active in one of the fractions anyway. Nonisotopic immunoassays that are carried out entirely in solution and do not require a separation stage are described as homogenous, and are advantageous because of the reduced number of steps required and hence the lower likelihood of operator error.

**Enzyme-multiplied immunoassay technique** Perhaps the best known homogeneous assay format is the enzyme-multiplied immunoassay technique (EMIT), in which the analyte is covalently attached to an enzyme, and the formation of an analyte–antibody complex blocks the active site and inhibits enzyme activity. When this blocked enzyme is mixed with the experimental sample, there is competition between the enzyme-linked analyte and the sample analyte for occupation of the antibody's antigen-binding site. The more of the analyte present in the sample, the more of the enzyme is released from inhibition, and the level of enzyme activity can thus be used to determine the quantity of the analyte.

A variation of the EMIT is the apoenzyme reconstruction immunoassay system, where the analyte is coupled not to the enzyme itself but to a cofactor or prosthetic group that is required for enzyme activity. For example, the analyte may be coupled to flavin-adenine dinucleotide (FAD), which is required for glucose oxidase activity. The antibody binds to the FAD–analyte conjugate and prevents FAD from interacting with the enzyme, whose activity is consequently reduced. The more analyte present in the sample, the more competition there is for the antibody and the more FAD–analyte conjugate remains free in solution and available to the enzyme. Again, the level of enzyme activity is related to the quantity of analyte in the sample.

**Fluorescence immunoassays** Fluorescent labels can also be used in homogeneous assay formats, and several different types of detection system can be employed. Direct fluorescence is a straightforward approach, which requires the formation or disruption of the analyte–antibody complex to generate the label. This is generally achieved by coupling the analyte to an inert fluorophore via an enzyme-cleavable bridge, which is rendered inactive by antibody binding. Perhaps the most common homogeneous, direct fluorescence-based immunoassay format is the substrate-labeled fluorescence immunoassay. The analyte is conjugated to a fluorogenic substrate of the enzyme  $\beta$ -galactosidase (4-methylumbelliferyl- $\beta$ -D-galactoside, more commonly known by its acronym MUG). The enzyme can cleave this substrate and release the fluorophore, methylumbelliferone, as long

as the analyte is not associated with its corresponding antibody. The more analyte present in the sample, the more MUG is free in solution and available to the enzyme, and the greater the direct fluorescent signal that is produced. When the fluorophore is excited by incident light at a particular excitation wavelength, energy is absorbed by electrons promoting them to an unstable higher energy state. When the electrons revert to their ground state, the energy is released as visible light with a characteristic emission wavelength that can be detected by a photomultiplier or charge-coupled device.

An alternative homogeneous fluorescence-based detection system is fluorescence resonance energy transfer (FRET). This phenomenon occurs when two fluorophores are in close proximity, and the donor fluorophore has an emission spectrum that overlaps the excitation spectrum of the acceptor fluorophore. When the donor fluorophore is excited, energy is transferred from donor to acceptor with the result that the intensity of emission from the donor is reduced (quenched). If both the analyte and antibody are coupled to fluorophores with overlapping spectra, then FRET will occur only when the complex forms. Thus, FRET has not been applied widely in conventional immunoassays.

A further fluorescence effect, fluorescence polarization (FP), has recently been employed in immunoassays. FP occurs when a fluorophore is excited by plane-polarized light and emits fluorescence that is also polarized. Complete FP occurs only when the fluorophore is stationary. The degree of observed FP is therefore dependent on how fast a molecule tumbles in solution, a property related to its molecular mass. Changes in molecular mass, for example, caused by antibody–analyte complex formation, can therefore be detected by changes in FP as long as the temperature, viscosity, and other conditions remain constant. This is the principle of the fluorescence polarization immunoassay, in which the analyte disrupts a tracer complex introduced into the sample, reducing the degree of FP as a function of analyte concentration.

**Other homogeneous immunoassays** Several further homogeneous assay formats have been developed that capitalize on the ability of antigen–antibody complexes to form detectable clusters or networks. Examples include the latex particle agglutination assay and the latex particle agglutination inhibition assay, in which the analyte or the antibody is conjugated to latex beads, and the analyte is quantified by virtue of its ability to promote or disrupt agglutination. Another example is the liposome immunoassay, in which analyte molecules are coupled to lipids,

**Table 1** Summary of ELISA assay formats and requirements

<i>ELISA protocol</i>	<i>Uses</i>	<i>Reagents required</i>	<i>Notes</i>
Indirect	Antibody screening	Antigen (pure or semipure)	Does not require preexisting specific antibodies
	Epitope mapping	Test solution containing antibody Enzyme conjugate that binds Ig of immunized species	Requires relatively large amounts of antigen
Direct competition	Antigen screening	Antigen (pure or semipure)	Rapid assay with only two steps
	Detect soluble antigen	Test solution containing antigen Enzyme–antibody conjugate specific for antigen	Excellent for measuring antigenic cross-reactivity
Antibody sandwich	Antigen screening	Capture antibody (purified or semipurified)	Most sensitive antigen assay
	Detect soluble antigen	Test solution containing antigen Enzyme–antibody conjugate specific for antigen	Requires relatively large amounts of pure or semipure specific capture antibody
Double sandwich	Antibody screening	Capture antibody (specific for Ig of immunized species)	Does not require purified antigen
	Epitope mapping	Test solution containing antigen Enzyme–antibody conjugate specific for antigen	Relatively long assay with five steps
Direct cellular	Screen cells for antigen	Cells expressing antigen of interest	Sensitive assay for bulk screening
	Measures antigen levels	Enzyme–antibody conjugate specific for cellular antigen	Insensitive to heterogeneity of expression in mixed cell population
Indirect cellular	Screen for antibodies	Cells for immunization	May not detect antibodies specific for cellular antigens expressed at a low density
	against cellular antigen	Test solution containing antibody Enzyme conjugate that binds Ig of immunized species	

allowing them to form an artificial plasma membrane or liposome. The liposome is used to compartmentalize an enzyme that is separated from its substrate. Addition of the antibody causes the liposome to be disrupted and the enzyme released. As in other competition assays, the more analyte present in the sample, the less of the tracer will be sequestered into antibody–analyte complexes, and the lower the resulting enzyme activity. Although many researchers have used this method, it suffers from the inherent disadvantage of liposome instability.

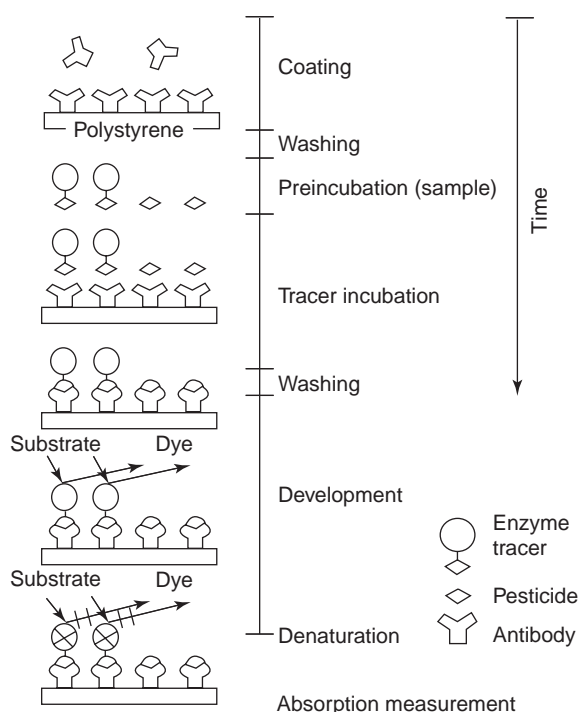

### Solid-Phase Assays with Nonisotopic Labels

Solid-Phase assays, which utilize a solid substrate to capture the reaction or reaction products, have also been adapted to work with nonisotopic labels. Either the antibody or the analyte can be immobilized on the solid phase, by adsorption or using a covalent bond. Both competition-type and immunometric-type assays can be performed using the solid-phase approach.

**Enzyme-linked immunosorbent assay (ELISA)** The most widely used heterogeneous solid-phase immunoassay format is the ELISA, which was first described in 1971. Usually, the antibody is immobilized on the solid phase, and is used to capture the unlabeled analyte from the sample. Six common variants of the technique are practiced, i.e., the direct competitive ELISA, the

sandwich ELISA, the double-sandwich ELISA, the indirect ELISA, the indirect cellular ELISA, and the direct cellular ELISA. The differences between these methods are summarized in **Table 1**.

The principle of the direct competitive ELISA is similar to that of the original radioimmunoassay except that the separation of bound and unbound labels is achieved by immobilizing the antibody (**Figure 2**). The substrate, often a microtiter dish, is first coated with analyte-binding antibody (in commercial kits the substrate usually comes ready-prepared). The sample is then added, allowing the analyte to bind to the antibody. A predefined amount of tracer is then added, which comprises a known concentration of enzyme-labeled analyte. Competition ensues between the sample analyte and the tracer because only limited numbers of antibodies are available. Following an incubation period, which may last several hours to allow the system to come to equilibrium, the excess reagents are washed away. The retained tracer population is inversely proportional to the amount of analyte in the sample, because the greater the amount of analyte, the fewer antibody sites will be occupied by the tracer. The amount of bound tracer is determined using the appropriate enzyme substrate reaction, which is usually colorimetric or chemiluminescent, and can therefore be quantified using a photometer or luminometer. More than half of ELISA tests employ horseradish peroxidase because of its high turnover number and the range of

**Figure 2** Principle of the competitive ELISA. (Reproduced with permission from Wiley-VCH; © Wiley-VCH.)

sensitive detection systems available, while alkaline phosphatase is also very popular.

The sandwich immunoassay, which requires two analyte-specific antibodies, is the most popular ELISA variant used for the quantification of large molecules, such as proteins (**Figure 3**). This is a non-competitive assay similar in principle to the IRMA. Two antibodies are required that recognize different epitopes on the target analyte and they must be able to bind simultaneously. The first antibody is immobilized on the microtiter plate, which is flooded with the sample in order to capture the analyte. After washing, the second antibody is added, which binds to the captured analyte and provides a quantitative signal. In the IRMA, this second antibody emits a radioactive signal that provides a surrogate quantitation for the analyte. In the ELISA, the second antibody is usually unlabeled, but is detected by a third, enzyme-conjugated antibody, facilitating a further level of signal amplification.

A number of additional strategies for signal amplification in ELISAs have been developed. One example is the use of secondary antibodies conjugated to biotin, a molecule that has very strong affinity ( $>10^{15} \text{ l mol}^{-1}$ ) for the egg yolk protein avidin. After application of the secondary antibodies and washing to remove unbound reagents, the substrate is flooded with an excess of enzyme-conjugated avidin. Not only is the interaction between avidin and biotin

**Figure 3** Principle of the noncompetitive sandwich ELISA. (Reproduced with permission from Wiley-VCH; © Wiley-VCH.)

molecules highly specific and irreversible, but each avidin molecule has multiple biotin-binding sites. Therefore, further amplification can be achieved by adding enzyme-conjugated biotin to the assay.

Another variation of the sandwich assay is the immuno-RCA technique, which involves a tertiary level of detection by rolling circle amplification. The principle is that an analyte, captured by an immobilized antibody, is recognized by a second antibody in a sandwich assay as above, but the second antibody has an oligonucleotide covalently attached to it (**Figure 4**). In the presence of a circular DNA template, a strand-displacing DNA polymerase, and the four dNTPs, rolling circle amplification of the template occurs resulting in a long concatemer comprising hundreds of copies of the circle, which can be detected using a fluorescent or enzymatically labeled oligonucleotide probe. Solid-phase direct fluorescent-detection immunoassays are becoming increasingly popular with the development of analytical protein biochips (see below).

**Magnetic particle immunoassay** Another variant of the solid-phase immunoassay format depends on coupling antibodies to magnetic particles. The assay

**Figure 4** Sensitive protein detection using the RCA (rolling circle amplification) immunoassay chip and solid-phase direct fluorescence detection. The chip is divided into 16 teflon wells, each containing an array of 256 antibodies as probes. When a protein, represented by the blue square, is captured by one of the probes, it can be recognized using a second, biotinylated antibody (red), which is subsequently detected by a tertiary universal antibody connected to a circular oligonucleotide. A strand-displacing DNA polymerase can use this circular template, generating a long concatamer containing many fluorescent labels.

is carried out in solution, but the beads represent the solid phase. The sample is first mixed with a tracer, which comprises the analyte conjugated to horseradish peroxidase. After thorough mixing, the antibody-magnetic particle suspension is added and allowed to form complexes. The particles are then precipitated with a magnet, washed, and reprecipitated, and then resuspended in the enzyme substrate buffer. The depth of color, or the degree of chemiluminescence, is inversely proportional to the concentration of analyte in the sample, since the greater the concentration of the analyte, the less of the tracer remains attached to the antibody-magnetic particle complexes.

## Highly Multiplexed Immunoassays

Miniaturized, multiplexed, solid-phase immunoassays were developed in the 1980s using protein microdots spotted manually onto nitrocellulose sheets and other solid supports. It was shown quite clearly that this multianalyte immunoassay format was far more sensitive than standard immunoassays carried out in microtiter dishes because the sample volumes were so much smaller. Over the last few years, these devices have evolved into protein biochips, in which microdots of antibodies or protein analytes are arranged in a dense miniature grid on a solid support such as a microscope slide. Two types of

immunoassay-type protein biochip can be distinguished: antibody arrays, which are used predominantly for the quantitative analysis of proteins (but also other analytes), and antigen arrays, which are used to profile antibodies in serum and other fluids.

Developments in protein biochip technology have resulted in some novel detection methodologies for the quantification of analytes. There are three broad classes of detection methods. In the first method, the proteins in the sample are labeled universally, either with a radioisotope, or an enzymatic or fluorescent conjugate, and the signal is detected directly from the bound analyte molecules on the chip. In the second method, the proteins are not labeled, but a sandwich reaction is used to detect molecules bound to the array and the signal is produced by the labeled detection reagent (essentially the same as a standard sandwich ELISA or solid-phase fluorescent immunoassay, although highly multiplexed). Finally, several label-free detection methods can be used to detect and/or identify proteins bound to antibodies or protein analytes on the chip surface.

Although radiolabels and colorimetric assays can be used with low-density protein chips, fluorescent labels are safer, more convenient, and provide a better spatial resolution. The label can be incorporated directly into the analyte or into a secondary detection reagent that is applied to the chip after it has been washed to remove unbound proteins. There are advantages and disadvantages to both methods. The advantage of direct labeling is that protein detection and quantification can be carried out in a one-step reaction, and multiplex analysis is possible. A disadvantage of direct labeling is that not all proteins are labeled with the same efficiency, and the label itself can alter the structure of some proteins and interfere with their binding capabilities. These problems do not arise when a sandwich assay is used, so this approach may be preferable where accurate quantitation is needed. However, the main disadvantage of sandwich assays is the requirement for two antibodies recognizing different epitopes for each protein captured on the chip, a problem that increases in magnitude as the number of simultaneously analyzed proteins gets larger.

Label-free methods use the intrinsic properties of proteins to report binding events on protein chips. Ciphergen 'ProteinChips' can be incorporated directly into a matrix-assisted laser desorption/ionization (MALDI) source of a mass spectrometer, which can identify the proteins and provide quantitative analysis. The ionization of proteins bound to 'ProteinChips' is enhanced by the properties of the chip surface, leading to more uniform mass spectra than possible with standard MALDI mass spectrometric

analysis, a phenomenon described as surface-enhanced laser desorption/ionization. The quality of mass spectra is improved even further by incorporating the matrix compound into the chip surface, a technique called surface-enhanced neat desorption.

BIA-Core Inc., Uppsala, Sweden, produces a range of protein chips on which protein interactions can be detected by changes in surface plasmon resonance (SPR). This is an optical effect that occurs when monochromatic polarized light is reflected from thin metal films. Some of the incident light energy interacts with the plasmon (the delocalized electrons in the metal), which results in a slight reduction in reflected light intensity. The angle of incidence at which this shadowing effect, the SPR, occurs is determined by the material adsorbed onto the metal film, which in this case is one or more antibodies. There is a direct relationship between the mass of the immobilized molecules and the change in resonance energy at the metal

surface, which can be used to study interactions in real time. Thus, when light is shone on a gold-coated glass chip from underneath, the angle of incidence that induces SPR will change when analytes bind to antibodies on the chip surface, and the change will reflect the molecular mass of the analyte (Figure 5). Direct coupling of SPR spectroscopy and mass spectrometry allows interacting proteins to be characterized.

### Introduction

The aim of this article is to give a review of the current techniques used for the generation of antibodies

and antibody fragments. It describes the methodology involved in antibody production. This includes the choice of antigen and adjuvant and updated screening, purification, and characterization approaches.

### Antibody Structure

Although antibodies can vary in structure, they are generally typified by the immunoglobulin G (IgG)

**Figure 1** Basic structure of an antibody. The molecule consists of two identical heavy chains and two identical  $\kappa$  or  $\lambda$  light chains and has a molecular weight of 150–160 kDa. The antibody chains can be further divided into constant (C) and variable (V) regions based on their amino acid variability. The variable regions, located at the N-terminal portions of both the heavy and light chains, create the scaffolding for the antigen-binding site, which is formed by six hypervariable loops or CDRs. The Fc region of the molecule, which contains the C<sub>H2</sub> and C<sub>H3</sub> domains, plays a number of important physiological roles in immunological responses.

molecule, the most abundant subclass found in the serum of mammals. The basic four-polypeptide chain structure of an antibody is shown in **Figure 1**. It consists of two identical heavy chains and two identical light chains, which are held together by a number of disulfide bonds. The antibody chains can be further divided into constant (C) and variable (V) regions based on their amino acid variability. The variable regions, which are located at the N-terminal portions of both the heavy and light chains, form the antigen-binding fragment (Fab), one of the most important regions of the molecule. Within this region there are areas of hypervariability, referred to as the hypervariable loops or the complementarity determining regions (CDRs), which are primarily involved with binding antigen. It is the variation in the amino acid sequence of the CDRs that allows for the generation of a multitude of different antibodies with different binding specificities. The remainder of the variable heavy and light domains exhibit far less variation, and these stretches are known as the framework regions (FRs). The crystallizable fragment (Fc) of the antibody is involved in binding surface receptors and plays a number of important physiological roles in immunological responses. This Fc portion is linked to the two Fab domains by a hinge region, which provides flexibility, allowing binding sites on each Fab arm to work independently of each other.

## Antigens

Antigens can be defined as molecules that contain distinct sites or epitopes that are recognized and

interact with various components of the immune system. Immunization of an animal with a single antigen yields monospecific antiserum while mixtures of antigen, such as a cell or unpurified crude preparations, yield multispecific or polyspecific antiserum. However, not all antigens present can be presumed to elicit the same immune response, and the degree of response to a particular antigen may differ from one to another. Generally proteins and large molecules are capable of eliciting good immune responses with the aid of adjuvants (immune stimulants). Smaller molecules, such as drugs, with a molecular weight of less than 5000 Da, are often too small to cause an immune response on their own. They are referred to as 'haptens' and require conjugation to larger carrier molecules to render them immunogenic. Various carrier proteins, such as bovine serum albumin (BSA), ovalbumin (OVA), keyhole limpet hemocyanin (KLH), or thyroglobulin, are commonly used for this purpose. However, other carriers composed of synthetic or natural polymers (e.g., dextran, poly-L-lysine), lipid bilayers, or synthetic organic molecules have also been used. Regardless of the type of molecule, a carrier must be highly immunogenic, have the required solubility properties, be nontoxic *in vivo*, and possess suitable functional groups for coupling to the hapten.

There are a variety of coupling chemistries available for coupling haptens to carrier molecules. The choice of method is governed by the functional groups available on both the hapten and the carrier and the orientation of the hapten desired for presentation to the immune system. Conjugation procedures employing

the carbodiimide EDC (1-ethyl-3-(3-dimethyl-amino-propyl)carbodiimide hydrochloride) are commonly used for immunogen formation, as the method is both efficient and relatively simple. Another advantage of this cross-linking methodology is that no bridging molecule is introduced between the hapten and carrier, thus eliminating the potential of antibodies being generated against the coupling reagent, which could dilute the desired antibody response against the hapten. However in some cases the linker molecules between the hapten and the carrier may be necessary to increase exposure of the hapten and, thus, its immunogenicity.

Conjugation is a crucial step in antibody production as the specificity of the resultant antibodies is dependent on the hapten used to produce them. The one major problem associated with using conjugates for antibody production is that antibodies will be produced against both the hapten and the carrier molecule. To reduce the production of nonspecific antibodies and direct the production of antibodies to the hapten rather than the carrier, the number of haptens conjugated to each carrier molecule can be optimized and different proteins used in conjugates for immunization and screening.

## Adjuvants

Although carrier molecules increase immunogenicity, as discussed above, adjuvants are still generally required to stimulate initially an immune response in an animal. Adjuvants are nonspecific stimulators and are used in immunization methods to maximize an immune response. The most commonly used adjuvants are Freund's complete and incomplete adjuvants, FCA and FICA, respectively. FCA, which is only used for the initial immunization, consists of heat-killed *Mycobacterium tuberculosis*, nonbiodegradable mineral oils, and an emulsifier. The purpose of the mycobacteria in the adjuvant is to cause an inflammation, which attracts macrophages and other cells to the injection site. The antigen, which is emulsified in the oil, is released slowly to give a prolonged exposure to the immune system. To minimize side effects in the animal, FICA, which contains no bacteria, is used for subsequent boosts. Other adjuvants include Hunter's TiterMax, liposomes, the RIBI adjuvant system, and *Bordetella pertussis*. The RIBI adjuvant system (RAS) has been used as a successful alternative to Freund's adjuvant, because it is less viscous and, therefore, easier to handle. Antiserum can also be successfully produced without the use of adjuvant. This can be achieved by immunization of the antigen immobilized on a solid matrix (e.g., sepharose beads, nitrocellulose). It should be

noted that adjuvant is not required when cells are being used as immunogens.

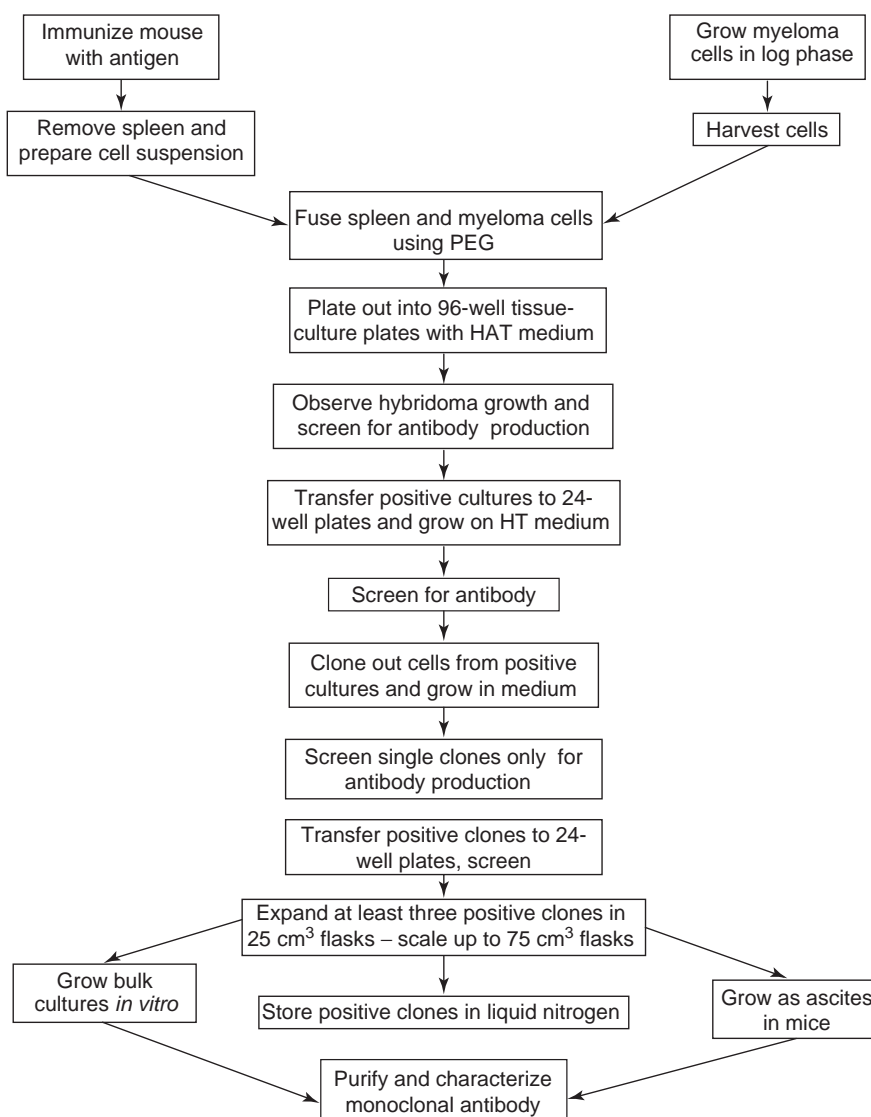

## Polyclonal Antibody Production

Polyclonal antibody production involves the repeated immunization of an animal with a desired antigen. Animals such as rabbits, goats, and sheep are generally used for polyclonal antibody production, as they are relatively easy to handle for immunization and bleeding purposes. When a sufficient titer (antibody concentration) is obtained, the animal is bled and the antibodies are purified from the serum. Polyclonal antibodies can be produced quickly and relatively cheaply and do not require the same amount of expertise or time as monoclonal antibody production. They can also be very specific and high concentrations can be purified from relatively small amounts of serum. However, polyclonal antiserum contains a heterogeneous population of antibodies, which can be hard to reproduce in subsequent immunizations. Unlike monoclonal antibody production, a consistent source of antibodies cannot be generated.

## Monoclonal Antibody Production

Antibodies secreted in response to immunization with a specific antigen are usually polyclonal, in that a mixed population of antigen reactive B-cells is stimulated, which recognize different epitopes on the immunogen. This system produces heterogeneous antibody populations, with a wide range of binding affinities. In monoclonal antibody production, however, the antibody molecule is derived from a single clone of B-cells and each antibody secreted by the clone has identical antigen-binding specificity. In other words, monoclonal antibodies provide single epitope specificity and potentially limitless amounts of identical antibody.

Monoclonal antibodies are most commonly produced by employing the hybridoma technique. **Figure 2** illustrates this technique. In this method, splenocytes (normal B-cells) from an immunized animal are fused with myeloma cells (tumor B-cells) using a fusion medium such as polyethylene glycol (PEG). Stock myeloma cell lines selected for the fusion process are specifically chosen because they are derived from a common ancestor MOPC-21 known to have lost the ability to produce IgG, so that the only antibody produced is derived from the antigen-sensitized splenocyte. The resultant hybrid cell is known as a hybridoma and inherits antigen specificity from the splenocytes and immortality from the myeloma cells, thus creating a

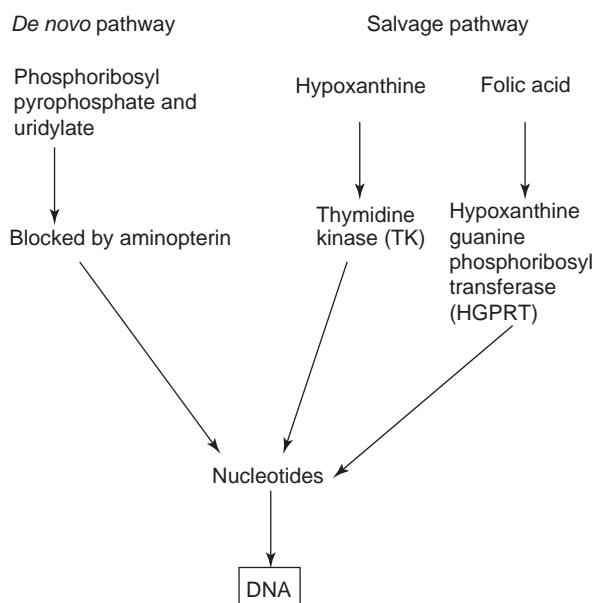

**Figure 2** Flow diagram illustrating the production of monoclonal antibodies using hybridoma technology.

permanent cell line, which secretes a homogeneous antibody of desired specificity.

Once the fusion has taken place, it is necessary to eliminate any unfused myeloma cells and to select only hybrid cells secreting antibody. This is primarily achieved by the use of hypoxanthine aminopterin thymidine (HAT) media and cells that are deficient in the enzyme responsible for incorporation of hypoxanthine into DNA. **Figure 3** illustrates this process. The unfused splenocytes are not immortal and naturally die off in culture. The elimination of the unfused myeloma cells is carried out by the initial use of mutant myeloma cells selected for a deficiency in the enzymes hypoxanthine guanine phosphoribosyl transferase (HGPRT) and thymidine kinase (TK), rendering them unable to use the salvage pathway for nucleic acid synthesis. The myelomas will die off

since the main pathway for purine and pyrimidine synthesis is blocked by aminopterin contained in the HAT media. Mammalian cells synthesize nucleotides by two different pathways. HAT medium contains aminopterin to block the *de novo* pathway and hypoxanthine and thymidine to allow growth by the salvage pathway. Cells that lack either HGPRT or TK will die in HAT medium, because they lack the ability to use the salvage pathway to acquire essential intermediates for the synthesis of nucleic acids.

Once selection is successful, it is necessary to perform initial screening to identify positively the hybridomas secreting the antibody of interest. Screening methods will be discussed in more detail later, but it is important to note that the results of initial screening are vital in determining what clones should be expanded. It is important to identify positive cultures as

**Figure 3** Schematic representation of HAT selection. HAT medium contains aminopterin to block the *de novo* pathway and hypoxanthine and thymidine to allow growth by the salvage pathway. Cells that lack either HGPRT or TK will die in HAT medium, because they lack the ability to use the salvage pathway to synthesize nucleic acids.

early as possible in order to concentrate on expanding the antibody-secreting hybrids, but it is equally important to eliminate nonsecreting clones at this stage to avoid overgrowth and wasting time and materials propagating them. When antibody activity has been determined, immediate cloning and retesting should take place. The type of assay used to detect the antibody should ideally be chosen to mimic the eventual application envisaged and should be standardized prior to hybridization.

Cloning is undertaken to ensure that all hybridomas are derived from a single parent that secretes the required antibody and that nonsecreting clones arising either in the original fusion wells or as spontaneous variants do not outgrow the antibody-secreting hybrids. This ensures that the hybridomas secrete antibody that is homogeneous and monospecific. Early cloning allows the selection of cells that have chromosomes for antibody production. Otherwise variants not producing IgG will overgrow. There are two common methods used to clone out hybridomas: soft agar and limiting dilution. In soft agar the cells are plated out on a semisolid medium such as low-agar plates. Single cells produce colonies that are further expanded. Limiting dilution involves seeding the cells at a known concentration in 96-well plates. It is important to seed at very low densities of less than one cell per well to ensure monoclonality. Growth conditions must be optimized to ensure that such low

cell densities can survive; this is achieved by the use of special media such as Briclone. However, it is necessary to carry out several rounds of cloning before a stable monoclonal hybrid can be assumed. Hybridomas can become unstable over time and hence stocks of original clone must be maintained by cryopreservation in liquid nitrogen.

Another method for producing hybridomas is as ascites tumors in mice. In this method, hybridomas are injected into animals. The antibody is contained in the rich ascites fluid that develops. Large doses of cells are required to initiate the tumor and it is important that the hybridoma and mouse are compatible. The productions of ascites tumors are facilitated by pretreatment of the mouse with, and intraperitoneal injection of, pristane. The ascites fluid is drained once sufficient swelling has been produced at the tumor site. The main concerns with this method are animal welfare issues, but the main advantage is that large amounts of antibody can be prepared.

## Problems Associated with the Production of Monoclonal Antibodies

There are several problems associated with monoclonal antibodies that can detrimentally affect production yields. It is vital to use fresh reliable cells because a low yield of hybrids can occur due to spontaneous drift in the myeloma cell line. A poor immunogen can also affect hybrid yield; however, a change in immunization schedule or strain of mouse can rectify this problem. The instability of hybrids can result in a complete loss of antibody secretion. This is usually due to overgrowth by nonsecreting cells, and therefore it is vital to plate out cells at high dilution postfusion. Many studies have been carried out to find optimal culture conditions for positive secreting clones. One such study indicated that in order to generate the largest possible number of positive hybrids, it is necessary to seed the cells in a concentration that will result in the growth of one hybrid clone per well. In a culture containing many clones, the number of hybrids actively secreting a specific antibody is relatively low; therefore, maximal yield of antibody is obtained by seeding at high dilution and low density.

Chromosome loss and gene segregation can have a significant effect on heavy and light chain synthesis in a cloned hybrid line, resulting in total loss of antibody production. The reason for this is that maximally producers (good antibody secretors) are terminally differentiated because they devote a higher percentage of protein synthetic activity to the antibody, rendering them more likely to die after a few generations in culture.

Mycoplasma contamination of cell culture systems continues to present major problems for monoclonal antibody production. Mycoplasma-positive cell cultures are themselves the major source of infection. It is recommended that all myeloma cell lines be tested for mycoplasma prior to fusion. If a hybridoma culture is considered irreplaceable, it is possible to eliminate effectively the mycoplasma contamination by injecting the hybrids into mice. The animal's immune system will destroy the infection and effectively clean up the cells. The mycoplasma-free cells are then recovered by draining the ascites fluid. Drug treatment is also an effective method to decontaminate hybrid cells from mycoplasma infection.

## Screening Methods

There are many principles to consider in selecting a suitable screening assay for the detection of hybridomas secreting antibodies of desired specificity. Speed and convenience are important factors to consider since hybrid clones mature and grow at different rates. Batch testing is possible, but not recommended as delays in screening can risk the loss of positive clones due to overcrowding or selective growth of nonsecreting cells. A standardized, reliable, sensitive assay is required that must be relevant to the format of the antibody application. There are three main types of screening method: antibody capture, antigen capture, or functional assays. Antibody and antigen capture assays are the most frequently used techniques but functional assays are becoming more common, whereby the antibodies in the hybridoma supernatants are used to block a reaction. Binding assays are suitable for monoclonal antibody screening as they detect all antibody activity against a particular antigen and can usually be modified for the use of isotype-specific IgG antibodies. Enzyme-linked immunosorbent assay (ELISA) techniques are well-established methods used to determine soluble or insolubilized antigens or antibodies. It is sometimes possible that sandwich assays are more suitable than direct assays for the initial screening of monoclonal antibodies, since the antigen is immobilized in a number of orientations using polyclonal antibodies, therefore allowing detection of the monoclonal with a wide range of specificities.

Live cell ELISA assays are used for the screening of monoclonal antibodies directed to cell surface antigens. This is advantageous for antigen detection on homogeneous cell lines or cell mixtures with a large number of positive secreting cells. Screening methods must be optimized and the chosen optimal conditions controlled. This is because the binding affinity of an

antibody can depend on physical parameters such as pH and temperature, thus varying the apparent specificity of the antibody if these conditions are altered. Current general screening methods include ELISA, radioimmunoassay, dot and Western blotting, flow cytometry, and arrays.

## Large-Scale Production

Once a monoclonal antibody with optimal properties has been selected and fully characterized, it is usual to scale up and attempt to produce the antibody-secreting hybridoma on a large scale. This can be achieved in a number of ways. Large amounts of monoclonal antibody can be produced either *in vivo* or *in vitro*. The concentration of monoclonal antibody produced in culture ranges from 1 to 20  $\mu\text{g ml}^{-1}$ , whereas *in vitro* production via ascites fluid yields between 1 and 20  $\text{mg ml}^{-1}$ . However, large-scale production involves a lot more than the simple culturing of large batches of cells or their injection into large numbers of mice.

A concern associated with culture technology is the problem of serum contamination. The presence of animal serum proteins can affect the purity of the monoclonal antibody. Recent studies, however, show that serum-free media can sustain certain hybridomas. The biggest issue in scaling up is the elimination of the water-soluble nongaseous products of cell metabolism. Two chamber devices are required to rectify this, but have proved difficult to fabricate and more complicated to operate than traditional methods. Novel large-scale culture systems such as the Tecnomouse, Berlin Tumbling Chamber, Bochum Glass Mouse, and miniPERM Bioreactor are now being used for monoclonal antibody production. These systems have semipermeable membranes that keep back the cells and the secreted antibody, but allow the passage of nutrients and metabolic products. In recent years, there have been a number of major advancements in large-scale production. There are variations in each design, but the principle is the same and most large-scale systems are agitated to enhance production. The principle of rotating cultures in scaled-up systems greatly increases the antibody yield, whereby eight times more IgG was produced in a roller bottle system when the cultures were continuously agitated.

The commercial production of monoclonal antibodies is carried out for two main reasons: antibodies are used in diagnostic test development and in the research of emerging antibody therapies. Glennie and co-workers have reported on recent advances in the commercial production of antibodies for therapeutic treatments. Currently, over 130 monoclonal

antibodies are undergoing clinical and commercial trials for approval by the US Food and Drug Administration (FDA). Reichert has reported on the approval of 11 monoclonal antibodies for use in the treatment of diseases and conditions such as cancer, Crohn's disease, and transplant rejection. The human immune system however tends to react to mouse-derived antibodies, which in turn leads to a decrease in the effectiveness of the therapy or therapeutic complications. Transgenic mice strains have been engineered to produce human gene repertoires in the absence of mouse antibodies, thus allowing the production of human antibodies to specific antigens while eliminating the problem of negative immune responses in humans. Jakobovits has described the production of a transgenic strain called xenomouse. This particular strain provides an excellent source for the manufacture of antigen-specific humanized monoclonal antibodies for therapeutic use.

## Antibody Engineering

Hybridoma technology has facilitated the production of large amounts of homogeneous antigen-specific rodent-derived antibodies for use as diagnostic and therapeutic agents. Although this technique has indeed proven invaluable, there are a number of drawbacks. Hybridomas are sometimes difficult and expensive to maintain in culture, but probably the main disadvantage with this technology is the difficulty in producing large quantities of stable human monoclonal antibodies, due to the absence of suitable myeloma cell lines. These disadvantages prompted the development of recombinant antibody technology.

Genetic engineering allowed the first generation of humanized monoclonal antibodies, referred to as chimeric antibodies. These antibodies consist of variable regions of a murine monoclonal antibody linked to the constant regions of a human IgG

molecule. A second generation of humanized antibodies soon followed, in which the antigen-binding loops (CDRs) of the murine monoclonal antibodies were grafted onto a human IgG molecule (Figure 4).

The main reason for the generation of these constructs was to attempt to circumvent the problem of inducing human anti-mouse antibody (HAMA) responses when murine monoclonal antibodies are used as therapeutic agents in human patients. However, they did not fully overcome this problem and it was not till much later, with the development of combinatorial display libraries, that the production of fully human monoclonal genetically derived antibodies was possible. This technology has allowed the generation of monoclonal antibodies from several species, including human, chicken, rabbit, and sheep. Advances in molecular biology, facilitated by the introduction of techniques such as polymerase chain reaction (PCR), have allowed the creation of large repertoires of antibodies from antibody variable genes bypassing hybridoma technology and, sometimes, even immunization. These libraries, combined with phage display techniques, attempt to reproduce the diversity of the immune system by displaying millions or even billions of antibody fragments on the surface of phage. This technology has now made it possible to select an antibody to almost any antigen from an antibody repertoire with a large number (greater than  $10^8$ ) of clones.

The first step in the construction of a combinatorial antibody display library is to obtain the genes encoding for an antibody fragment. These genes can be isolated from B-cells of immunized animals (immune libraries) or from nonimmunized donors (naive libraries). Alternatively, antibodies may be constructed artificially by the *in vitro* assembly of V-gene segments and D/J segments (synthetic libraries). Conventional hybridomas can also be used as a source of variable genes for the construction of antibody fragments. The variable antibody genes, which

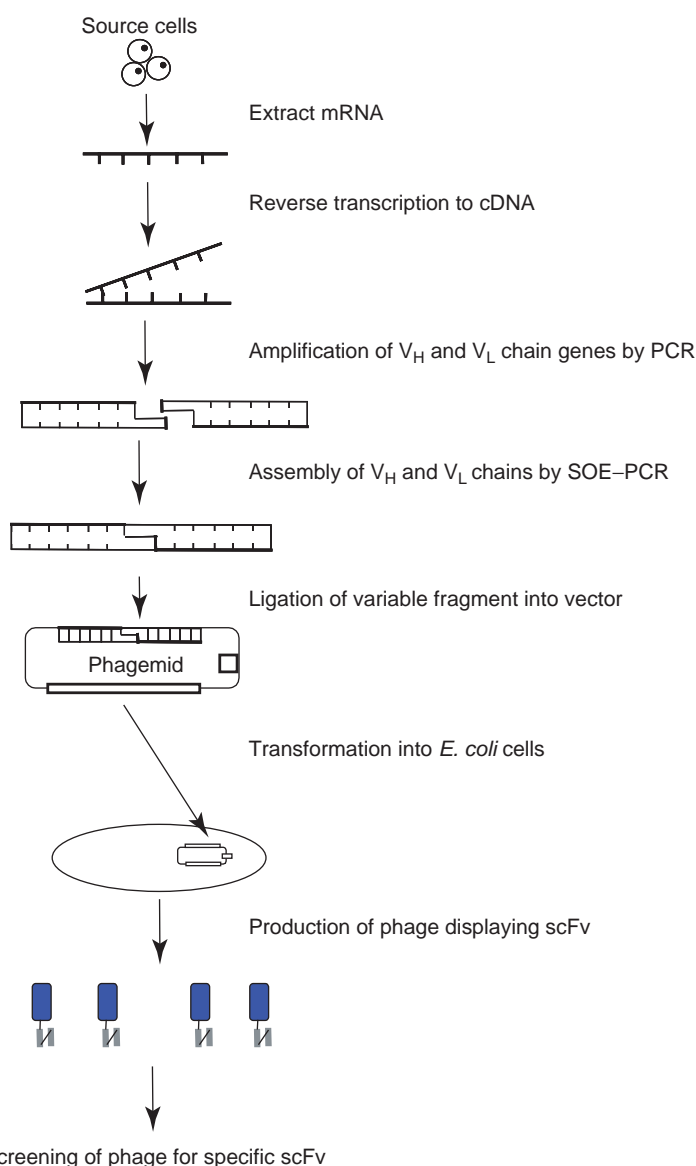

**Figure 4** Illustration of chimeric and humanized antibodies. Chimeric antibodies consist of variable regions of a mouse antibody linked to constant regions of a human IgG molecule, whereas humanized antibodies are almost entirely human except for murine CDRs.

should contain a full repertoire of antigen specificities, are first amplified using suitable primers. They are then randomly combined by splice by overlap extension-PCR (SOE-PCR), inserted onto a suitable plasmid, and applied to one of a variety of expression systems, including yeast (e.g., *Pichia pastoris*), bacterial cells (e.g., *Escherichia coli*), plant cells (e.g., *Nicotiana tabacum*), mammalian cells (e.g., COS cells), and baculovirus-infected insect cells.

The most widely used methodology for recombinant antibody library production utilizes filamentous phage, a bacteriophage that infects *E. coli*. The phage infect *E. coli* by attaching to the tip of the F pilus translocating the phage genome into the bacterial cytoplasm. *E. coli* is one of the most popular bacterial

expression hosts used, as it is easily manipulated and its fast growth allows the large-scale production of proteins. The method (Figure 5) involves cloning the genes encoding the antibody fragment into a particular vector as a fusion to the gene encoding one of the phage coat proteins (pIII or pVIII). Originally complete phage vectors were used as the display vector, but now small plasmid vectors or phagemids, which contain the appropriate packaging signal and cloning sites, are more commonly used. The phagemid encoding the antibody fragment-pIII fusion is packaged into phage particles using a particular helper phage (e.g., M13K07 or VCS-M13) and then used to transform a suppressor strain of *E. coli* (e.g., XL-1 blue). The resulting antibody fragment is expressed on the

**Figure 5** Schematic representation of the production of a combinatorial antibody phage display library.

**Figure 6** Structure of an antibody molecule and its various fragments. The  $F(ab')_2$  fragment comprises two disulfide-linked antigen-binding fragments, while the Fab fragment is only one antigen-binding fragment. Fab can be broken down into an Fv fragment consisting of the variable domains of the antibody. Incorporation of a hydrophilic peptide linker into the fragment produces an scFv. Other fragments include the Fd fragment, comprising a  $V_H$  and  $C_{H1}$  domain, and the CDRs, the smallest fragment capable of binding antigen.

surface of the phage, while its genetic material resides within the phage particle, providing a direct link between antibody genotype and phenotype. After expression, the displayed antibody fragment can be screened for antigen specificity by a process known as biopanning. This involves incubating the phage library in an immunotube coated with a specific antigen. Unbound phage particles are washed away, and bound phage are recovered from the surface, reinfected into the bacteria, and regrown for further enrichment. An antibody fragment with the best affinity and specificity can then be isolated and analyzed.

Prior to the development of recombinant technologies, antibody fragments could only be generated by proteolytic cleavage. Pepsin digestion of the IgG molecule produced a  $(Fab')_2$  fragment while papain digestion resulted in the generation of single Fab fragments. Now recombinant antibody technology can be used for the generation of a number of antibody fragments, which include Fab, Fv, and scFv, shown in **Figure 6**. The Fv fragment is the smallest fragment of an antibody that still contains the complete antigen site. However, the fragment, consisting of the variable domains of the light and heavy chain, can be quite unstable, as it lacks the disulfide bond present in the Fab fragment. This problem has been overcome by protein engineering. Disulfide bonds can be formed by the introduction of cysteine residues into the variable domains producing a disulfide-stabilized Fv fragment (dsFv). Another means of overcoming stability problems is to incorporate a flexible peptide linker of  $\sim 15$ – $20$  amino acids into

the Fv fragment resulting in a more stable single-chain variable fragment (scFv), the most commonly used configuration (**Figure 6**). Antibody engineering techniques have also been employed to manipulate the fragments to create dimeric, trimeric, and multimeric scFvs. These multimeric molecules can be specific for one particular target antigen or have multiple specificities to different antigens, by associating different scFv molecules derived from different parental antibodies. The range of antibody formats achieved by combining antibody fragments is virtually unlimited. Smaller antibody fragments, which have the ability to bind antigen, can also be engineered; these include the Fd fragment, consisting of a  $V_H$  and  $C_{H1}$  domain, and the CDR.

Recombinant antibody technology has several advantages, including the speed of antibody production, the possibility of altering affinity and specificity, and the ability to generate novel functionalities. Once the system has been set up in the laboratory, it can take weeks rather than months to produce an antibody fragment of desired specificity. With the development of new expression vectors, it is now also possible to express antibody fragments on a large scale, link the fragment to an enzyme allowing direct detection, or engineer a histidine (His) tag into the antibody sequence to facilitate purification by immobilized metal affinity chromatography (IMAC).

The emergence of this technology has made it possible to generate high-binding-affinity molecules against any chosen target, resulting in potentially

limitless applications. Recombinant antibodies have already contributed greatly in the analytical and diagnostic fields. They are especially ideal for tumor targeting, where small rapidly penetrating but high-affinity molecules are essential. However, further work in developing the technology is required and there are many challenges ahead before their full potential is reached.

## Antibody Purification

Purification of antibodies is carried out to enhance the reactivity of the antibody by removing any interfering immunoglobulins or contaminants. There are a number of methods available for antibody purification, and the choice of technique is dependent on a number of factors. These include the level of purity required, antibody class, antibody source, and intended application. Antibodies may be separated according to charge or size, using traditional protein purification techniques. A precipitation technique such as saturated ammonium sulfate (SAS) precipitation isolates the IgG molecules from other serum proteins, thus stabilizing the antibody and reducing lipid content.

Purification by ion-exchange chromatography is based on the fact that  $\gamma$  globulins (including antibodies) are the least negatively charged of the serum proteins. This makes them easy to purify using positively charged ion-exchange matrices. Affinity chromatography isolates a specific protein or group of proteins with similar characteristics. Affinity purification techniques can also be used to purify antibodies by capturing them on a gel matrix containing a covalently coupled analyte. Purified antigen can be acquired by coupling antibodies to an affinity

column. The most commonly used method of affinity purification exploits the ability of protein A and protein G to bind specifically to certain portions of the IgG molecule. When protein A and protein G are immobilized onto sepharose, the purification of monoclonal and polyclonal IgG-type antibodies is possible. There are several useful methods for recombinant antibody purification, many of which are similar to those used for monoclonal and polyclonal purification. The major technique currently used for scFv purification is IMAC. The affinity column involved in IMAC purification consists of transition metals, chelated by various acids. It is possible to engineer a histidine tag into an antibody fragment sequence and it is this His tag protein that binds the metal chelate column, thus facilitating purification.

Some of the other main techniques that are available are outlined in **Table 1**, along with their specific advantages and disadvantages.

There are also a number of commercially available antibody purification kits that have emerged in recent years; details of such kits are available from the manufacturers.

## Antibody Characterization

Characterization of antibodies is useful in determining antibody class, binding kinetics, epitope specificity, cross-reactivity, and antibody affinity. **Table 2** illustrates some of the techniques used to assess these characteristics.

Determination of the class and subclass of the antibody is performed in a number of ways, including radioimmunoassay, ELISA, and immune precipitation, using subclass-specific antisera. These are commercially available in the form of antibody isotyping kits.

**Table 1** Antibody purification techniques

<i>Technique</i>	<i>Usefulness</i>	<i>Advantages</i>	<i>Disadvantages</i>
Ammonium sulfate precipitation	Use as a single step, or with other methods	Cheap, easy, convenient for large volumes, nearly pure antibody	Moderate yields, multiple steps
Protein G	IgG isolation	High yields	Expensive, antibodies with high affinity to antigen are sometimes difficult to elute
Protein A	Pure IgG but low yield of IgG <sub>1</sub>	Binds bovine IgG weakly, high yields	Expensive, does not bind IgG <sub>1</sub>
IMAC	His tag recognition; recombinant antibody isolation	High yields, milder elution conditions	Formation of inclusion bodies, difficulty in solubilization
Gel filtration and DEAE	Relatively pure IgM	Cheap, useful for large volumes, extremes of pH not necessary	Less useful for separation of IgG classes
Antigen affinity chromatography	Useful for all types of antibody isolation	Binds specific antibodies	Must make specific antigen-linked column/matrix

**Table 2** Characterization of antibodies

Characteristic	Technique
Antibody specificity and cross-reactivity	Screening test against different related antigens using ELISA, RIA, BIAcore <sup>®</sup> , Western, and dot blotting
Antibody affinity	Kinetic studies, BIAcore <sup>®</sup>
Stability on storage	Testing of titre on recovery after storage
Monoclonality	Cross-absorption studies, subcloning and analysis, flow cytometry
Antibody class/subclass	Immune precipitation, RIA, ELISA

BIAcore<sup>®</sup> is a major manufacturer of advanced bioanalytical systems that provide real-time quantitative data on binding interactions between biomolecules using surface plasmon resonance (SPR) technology. For more information, see [www.biocore.com](http://www.biocore.com)

In the case of monoclonal antibodies, determination of the antibody class does not prove that the antibody is truly monoclonal. However, if the antibody was produced from a hybridoma that has undergone a rigorous and technically satisfactory cloning procedure and the antibody shows evidence of monoclonal specificity as established by a predetermined classification, it is assumed that the antibody exhibits monoclonality. The antibody specificity is investigated by performing cross-reactivity studies with the antigen and other structurally similar antigens using ELISA, RIA, BIAcore, Western, and dot blotting. The affinity of the antibody for its specific antigen can be investigated using ELISA or biosensors. BIAcore is a real-time SPR-based biosensor that can be used to study biomolecular interactions without the need for labeling. The antibody–antigen interaction can be studied using BIAcore, thus providing valuable information on the kinetics of association and dissociation.

## Introduction

Antibodies were used for the detection and quantitation of clinically important substances long before the development of immunoassays by Rosalyn Yalow and Solomon Berson in the 1960s and 1970s. However, since its first use for the measurement of insulin in blood, the immunoassay has become established as the most popular analytical technique applied in clinical medicine. Immunoassays are the first resort for the detection and measurement of a large number of hormones, blood products, enzymes, drugs, nutritional factors, and disease markers (**Table 1**). The popularity of the technique stems from its simplicity, rapidity, accuracy, and portability, the last allowing the technique to be adapted for ‘near-patient testing’. In most cases, immunoassays can be performed directly on untreated samples, such as plasma, serum, urine, saliva, and cerebrospinal fluid. While renowned for its ability to detect and quantify single analytes, more recent developments have seen the emergence of highly multiplexed immunoassays for the detection and quantification of hundreds or even thousands of analytes simultaneously. These novel platforms have permitted a shift in perspective, in which immunoassays are used to generate profiles of clinical samples that can facilitate accurate disease diagnoses and the prediction of drug responses.

## Types of Immunoassay Used in Clinical Applications

Immunoassays are analytical methods that achieve the detection and quantitation of analytes in clinical samples through the formation of a stable complex between the analyte and a specific antibody. The first

immunoassay techniques were based on the principle of competition between the analyte and a radio-labeled tracer with the same antigenic properties as the analyte. These two components would compete to occupy a limited number of antibody molecules. The amount of analyte present in the sample could be determined when the system reached equilibrium by separating the bound and unbound fractions of the tracer, and measuring the latter. The more analyte present in the sample, the more tracer would be displaced from the antibody and the greater the strength of the radioactive signal from the unbound fraction.

Such assays were described as heterogeneous because they depended on the separation of free and complexed tracer components, a process that was necessary because the label itself was unaffected by antibody binding. This is not necessarily true of non-isotopic labels such as enzymes and fluorophores, whose activities are often modified when the antigen to which they are attached interacts with its cognate antibody. Where antibody binding either inhibits or stimulates the signal generated by such a label, separation into free and complexed components is no longer necessary, and such assays are described as homogeneous. The main advantage of homogeneous assays is the absence of a separation step, which reduces the hands-on time and the likelihood of technical errors.

One of the disadvantages of the competition assays discussed above is that it is necessary to ensure that the amount of tracer added to the sample is not vastly in excess of the amount of analyte, and that the antibody is present at a lower molar concentration than the tracer. This means that very small amounts of reagents are used, which places high demands on the sensitivity of the assay. This problem was addressed by placing the label on the antibody rather than the analyte, as first demonstrated in the case of the immunoradiometric assay. In this format, quantitative data are generated by establishing a stoichiometric interaction between the analyte and the antibody. The signal produced by the antibody is thus directly proportional to the concentration of the analyte, rather than being related to it in a complex manner as is the case for competition analysis.

**Table 1** Representative list of immunoassays of major clinical interest

<i>Substance</i>	<i>Sample</i>	<i>Clinical indications</i>
<i>Polypeptide hormones</i>		
ACTH	Plasma	Distinguishes Cushing syndrome and Addison's disease
AVP	Plasma	Differential diagnosis of diabetes insipidus
Calcitonin	Plasma	Diagnosis of medullary carcinoma of the thyroid
C-peptide	Plasma	Differential diagnosis of hypoglycemia
Erythropoietin	Plasma	Investigation of anemia/polycythemia
FSH	Plasma	Investigation of infertility
Gastrin	Plasma	Diagnosis of Zollinger–Ellison syndrome
Glucagon	Plasma	Diagnosis of glaucoma
Growth hormone	Plasma	Diagnosis of acromegaly
	Urine	Diagnosis of growth hormone deficiency
hCG	Urine	Confirmation of pregnancy
Insulin	Plasma	Differential diagnosis of hypoglycemia
IGF-I	Plasma	Monitoring acromegaly, response to hCG therapy
IGF-II	Plasma	Differential diagnosis of hypoglycemia
LH	Plasma	Investigation of infertility
Neurotensin	Plasma	Investigation of diarrhea
Pancreatic polypeptide	Plasma	Diagnosis of APUDomas
Parathyroid hormone	Plasma	Differential diagnosis of hypo/hypercalcemia
Proinsulin	Plasma	Differential diagnosis of hypoglycemia
Prolactin	Plasma	Investigation of infertility, galactorrhea
Somatostatin	Plasma	Diagnosis of somatostatinoma
TSH	Plasma	Investigation of thyroid disease
VIP	Plasma	Differential diagnosis diarrhea
<i>Steroids</i>		
Aldosterone	Plasma	Investigation of hypertension, hypokalemia
Androstenedione	Plasma	Investigation of hirsutism, virilism, infertility
Bile-salts	Plasma	Investigation of liver disease
Cortisol	Plasma	Diagnosis of Cushing syndrome and Addison's disease
DHAS	Plasma	Investigation of hirsutism, virilism, infertility
11-Deoxycortisol	Plasma	Investigation of virilism
Dihydrotestosterone	Plasma	Investigation of virilism, impotence, feminization
17 $\alpha$ -Hydroxyprogesterone	Plasma	Investigation of congenital adrenal hyperplasia
Estradiol	Plasma	Investigation of infertility
Progesterone	Plasma	Investigation of infertility
Testosterone	Plasma	Investigation of virilism, impotence, infertility
<i>Amino/fatty acid derivatives</i>		
5-HIAA	Urine	Diagnosis of carcinoidosis
Melatonin	Plasma, urine	Investigation of sleep disorders
Reverse T <sub>3</sub>	Plasma	Investigation of thyroid disease
Thyroxine	Plasma	Investigation of thyroid disease
Triiodothyroxine	Plasma	Investigation of thyroid disease
<i>Proteins</i>		
Apolipoprotein A1	Plasma	Assessment of coronary heart disease risk
Apolipoprotein B	Plasma	Assessment of coronary heart disease risk
CK-MB	Plasma	Differential diagnosis of chest pain
C-reactive protein	Plasma	Monitoring response to anti-inflammatory therapy
Ferritin	Plasma	Investigation of iron storage capacity
Lipoprotein	Plasma	Assessment of coronary heart disease risk
Sex-hormone-binding globulin	Plasma	Investigation of hirsutism, virilism, infertility
Thyroxine-binding globulin	Plasma	Investigation of thyroid disease
Thyroglobulin	Plasma	Investigation of thyroid disease
Trypsin	Plasma	Investigation of thyroid disease
<i>Disease markers</i>		
$\alpha$ -Fetoprotein	Plasma	Investigation of liver cancer and other cancers
$\beta$ -2-Microglobulin	Plasma, CSF	Prognosis of myeloma and lymphoma, neuronal involvement
CA 15-3	Plasma	Monitoring breast cancer
CA 125	Plasma	Monitoring ovarian cancer

**Table 1** Continued

<i>Substance</i>	<i>Sample</i>	<i>Clinical indications</i>
CA 549	Plasma	Monitoring breast cancer
CEA	Plasma	Monitoring colorectal cancer
HCG	Plasma	Monitoring choriocarcinoma
MCA	Plasma	Monitoring breast cancer
NSE	Plasma	Monitoring neuroectodermal tumors
PSA	Plasma	Monitoring prostate cancer
SCC	Plasma	Monitoring squamous cancer of cervix, lung etc.
<i>Nutritional factors</i>		
Vitamin B <sub>12</sub>	Plasma	Investigation of anemia, B <sub>12</sub> status
Folic acid	Plasma	Investigation of anemia, folate status, malabsorption
Vitamin D	Plasma	Investigation of metabolic bone disease
25-Hydroxy-vitamin D	Plasma	Investigation of metabolic bone disease
1,25-Dihydroxy-vitamin D	Plasma	Investigation of hypercalcemia and bone disease

ACTH, adrenocorticotrophic hormone; APUD, amine precursor uptake and decarboxylation; AVP, arginine vasopressin; CEA, carcinoembryonic antigen; CK-MB, creatine kinase MB isoform; CSF, cerebrospinal fluid; DHAS, dehydroepiandrosterone sulfate; hCG, human chorionadotrophin; HIAA, hydroxyindoleacetic acid; FSH, follicle-stimulating hormone; IGF, insulin-like growth factor; LH, lutenizing hormone; NICTH, non-islet-cell tumor hypoglycemia; NSE, neuron-specific enolase; PSA, prostate-specific antigen; SCC, squamous cell carcinoma; TSH, thyroid-stimulating hormone; VIP, vasoactive internal polypeptide.

The immunometric-type assay has also been adapted for use with nonisotopic labels and is typically carried out in a heterogeneous format in which the antibody is immobilized on a solid support, such as a microtiter dish, membrane, or collection of beads. The canonical clinical immunoassay format in today's laboratories is the enzyme-linked immunosorbent sandwich assay, which employs two antibodies, one to capture the analyte and the other to detect and quantify it. More details of the principles of these and other immunoassay techniques are given elsewhere in this encyclopedia.

## Specific Applications

### Detection of Polypeptide Hormones

The first clinical immunoassays were developed for the detection of relatively large polypeptide hormones such as insulin and glucagon, since these are naturally immunogenic and can therefore stimulate the production of antibodies when injected into animals. Antibodies with binding characteristics suitable for competition assays were produced for a range of polypeptides with molecular masses in excess of 3 kDa, but this was not a suitable approach for the production of antibodies against smaller peptides, thyroid hormones, or small-molecule drugs. Solid-phase immunoassays have also been developed for a broad range of polypeptide hormones. The most widely used of these is probably the test for human chorionadotrophin (hCG) in urine, which is the underlying principle of home pregnancy-test kits.

### Detection of Steroid and Amino Acid/Fatty Acid-Derived Hormones

With the rediscovery of Landsteiner's observations that even very small molecules could be rendered immunogenic by linking them covalently to a protein, it became possible to develop immunoassays for almost every molecule of clinical interest. The main medical application of immunoassays remained in endocrinology, producing a revolution in clinical practice by facilitating the detection and quantitation of steroids (such as aldosterone and cortisol) and of hormones derived by the biotransformation of single amino acids and fatty acids (such as thyroxine, melatonin, and 5-hydroxytryptophan). Not only is it possible to measure these hormones at the infinitesimally low concentrations at which they naturally occur in tissues, plasma, and other body fluids, but the assays are sufficiently rapid and economical to be useful in day-to-day patient care.

### Detection of Therapeutic Agents and Drugs of Abuse

Once the raising of antibodies to small molecules ceased to be a technical problem, the application of immunoassays to the detection and measurement of drugs in body fluids as part of the process of therapeutic drug monitoring became commonplace. The number of drugs for which immunoassays have been developed is extensive, although comparatively few have found a place in regular clinical practice (Table 2). Similar techniques have been employed for the semi-quantitative detection of drugs of abuse in urine, blood, saliva, and body tissues. In this context,

**Table 2** Clinically useful drug immunoassays

<b>Therapeutic drug monitoring</b>		
<i>Anticonvulsants</i>		
Carbamazepine	Ethosuximide	Phenobarbitone
Phenytoin	Primidone	Valproic acid
<i>Antibiotics</i>		
Amikacin		Chloramphenicol
Gentamicin		
Netilmicin	Tobramycin	Vancomycin
<i>Cardioactive drugs</i>		
Digoxin	Diisopyramide	Lignocaine
Procaineamide	Quinidine	
<i>Psychoactive drugs</i>		
Amitriptyline	Desipramine	Imipramine
Nortriptyline		
<i>Others</i>		
Caffeine	Cyclosporin A	Methotrexate
Theophylline		
<b>Drugs of abuse screening</b>		
Amphetamines	Barbiturates	Benzodiazepines
Canabinoids	Cocaine	LSD
Opiates	Phencyclidine	

immunoassays are advantageous over most of the other available methods for drugs testing because they are sensitive, inexpensive, and simple to perform. This has led to them being used as screening techniques in sport, where drug abuse is common, as well as in more commonplace clinical settings.

### Blood Products, Enzymes, and Other Proteins

Increasingly, plasma proteins that were once measured exclusively by their catalytic activities and expressed in terms of enzyme units are now being measured by immunoassay techniques, and expressed in terms of concentration (e.g., micrograms per liter). When the results from these very different forms of analysis are compared, there is often little correlation. In many cases, this reflects the fact that proteins can exist in multiple structural forms, differing in conformational properties, in terms of proteolytic cleavage, or in terms of specific forms of post-translational modification (e.g., phosphorylation). While these forms may retain some conserved epitopes, and thus have common immunological properties, structural differences often have a profound effect on their activities. For example, it has been found that the blood protein factor VIII, which is one of the key proteins in the blood clotting cascade, loses its catalytic activity in hemophilia while

retaining many of its immunological properties. Consequently, while factor VIII may appear to be absent from the blood when measured in terms of its ability to convert fibrinogen into fibrin, is found to be present at normal levels when measured by immunoassay.

### Disease Markers

In the context of disease, immunoassays were first used for the management of patients suffering from choriocarcinoma, whose tumors produce excessive amounts of hCG. Until the 1970s, this disease was invariably fatal within a few months of diagnosis. However, with the advent of specific chemotherapeutic treatments for tumors of trophoblastic origin and the development of ultrasensitive immunoassays for hCG in plasma as a guide to how long therapy should be continued, the prognosis for complete recovery is now greater than 90%. By ensuring that treatment continues until hCG can no longer be detected, it becomes possible to eliminate every neoplastic cell in the body and avoid recurrence.

The application of immunoassay techniques to the detection and quantification of antigens specifically present or absent in disease has grown enormously since these early successes. Indeed, at the current time, it is estimated that over 1000 recombinant antibodies recognizing disease-specific targets are being developed by biopharmaceutical companies around the world. A large proportion of these antibodies recognize cancer antigens but others have been developed for the diagnosis (and treatment) of infectious diseases, autoimmune disorders, as well as blood, neurological, cardiovascular, skin, respiratory, and eye diseases.

Immunoassay techniques can be used not only for the detection and quantitation of disease-specific markers, but also for their discovery. This has been facilitated by the development of highly multiplexed immunoassay formats, otherwise known as antibody arrays. For example, an array containing 146 antibodies recognizing proteins involved in cell cycle regulation, stress response, and apoptosis has been produced for the screening of tumor samples. VoLo carcinoma cells were irradiated with a cobalt-60 source and cultured for 4 h before protein extracts were obtained and labeled with the fluorogenic molecule Cy3. Protein extracts from parallel cultures of nontreated cells were labeled with Cy5, which is similar to Cy3 but has a different emission wavelength, allowing protein levels in the two samples to be compared on the same array. These experiments identified 11 proteins that were upregulated in colon cancer, six of which were previously not known to be

involved. Most of these proteins had roles in apoptosis, and increased apoptosis of the cells was observed after radiation treatment. Another protein, the carcinoembryonic antigen (which is used in the immunodiagnosis of colorectal cancer), was shown to be downregulated.

Although there have been several reports of novel biomarkers identified using antibody arrays, it is rare to find a single diagnostic marker that is reliable in a clinical setting. However, the ability to determine the levels of hundreds of protein simultaneously allows the overall pattern of protein expression to be used as a diagnostic tool, a method known as pattern profiling (Figure 1). Disease diagnosis is achieved by feeding the antibody array into a mass spectrometer and looking at the mass spectra produced by surface-enhanced laser desorption/ionization (SELDI). This provides higher sensitivity than the analysis of single biomarkers, which are often expressed in multiple diseases making a precise diagnosis difficult. This is especially true in closely related diseases, such as different forms of cancer or dementia.

A useful example of SELDI pattern profiling is the early diagnosis of ovarian cancer, a disease that is usually detected at the late stage when cancer cells have already spread and the prognosis is poor. In the original study, mass spectra derived from the serum samples of women with ovarian cancer and from unaffected controls were used as a training set for a pattern-matching algorithm. A discriminatory pattern was identified, which was applied to another set of samples. This resulted in the correct diagnosis of all ovarian cancers (including 18 stage I cancers, where the prognosis is favorable because the neoplastic cells are still contained within the ovary) and a false positive rate of only 5%. Similar algorithms have been used to diagnose breast and prostate cancers. In each

case, the sensitivity of the pattern-profiling method has been significantly higher than tests relying on the presence of single biomarkers, and in at least one study the sensitivity of the method has been high enough to achieve 100% correct diagnosis. This new approach to disease detection could revolutionize the clinical laboratory, providing the means to process more samples than before and detect diseases earlier and more accurately than is currently possible using standard immunoassay methods.

## Limitations of Immunoassays in Clinical Settings

### Specificity

The early claims for the almost absolute specificity of immunoassays for particular antigens were based more upon what was then understood about the specificity of antibody–antigen interactions than on empirical evidence. For example, antibodies raised against insulin did not react against any other proteins known at the time, or against any other known substance. It soon became clear, however, that ‘specificity’ in the context of an immunoassay is a relative term. Nowhere was that message clearer than in relation to glucagon, which was among the first few polypeptide hormones for which radioimmunoassays were developed.

Antisera raised against pancreatic glucagon, the only form of the hormone known at the time, reacted with substances that could be extracted from the gut, and which were also present in the circulation, but with sufficient differences from native glucagon to suggest their nonidentity. These substances differed from glucagon not only immunologically but also in their biological properties. Portions of the molecule

**Figure 1** Protein patterns in disease diagnosis. A blood sample contains many proteins, which can be captured and quantified on an antibody array. The relative abundances of the proteins provide a unique signature, or fingerprint, which can be detected by specialized algorithms and used to diagnose disease and classify different forms of tumor. (Reproduced with permission from Twyman RM (2004) *Principles of Proteomics*. Abingdon, UK: BIOS/Garland Publishers.)

that were essential for biological activity were not necessarily immunogenic, while portions that were extremely immunogenic were seemingly irrelevant in terms of biological activity.

Because many molecular variants of a hormone with shared epitopes but different biological properties may exist in the plasma at the same time, it may be very difficult to measure any one of them accurately and precisely without their prior separation by chromatography or a similar method. Investigations stemming from the problem of immunoassay specificity have undoubtedly led to a greatly increased understanding of the nature of immunological determinants or epitopes. The knowledge so gained has made it possible to develop improved immunoassays with more appropriate specificities. This has been particularly important, for example, in the development of immunoassays for parathyroid hormone in plasma, where an ability to differentiate between the active hormone and its inactive degradation products is essential if the results of the assay are to have any clinical validity. Ironically, while the situation for insulin is similar (in that insulin immunoassays pick up not only mature insulin, but also proinsulin and split insulin fragments that continually circulate in the plasma) the pan-specificity of the immunoassay has been clinically beneficial, as the following example shows.

Despite the enormous contribution that the ability to measure insulin has made to our understanding of disease (especially diabetes), the most reliable clinical indication for abnormally high insulin levels is hypoglycemia (low blood glucose). One of the most important of the uniformly rare diseases causing hypoglycemia is a small benign tumor of the pancreas often referred to as an insulinoma. Left untreated, such tumors can cause potentially fatal hypoglycemia, but they can be cured by surgical excision. The biochemical hallmark of insulinoma is the continued secretion of insulin in the presence of low blood glucose, which normally inhibits it. However, many such tumors produce large amounts of proinsulin, either alone or in addition to insulin. Therefore, the ability of insulin immunoassays to detect these tumors relies upon the antibody recognizing proinsulin as well as the mature form. If the clinical insulin assays were absolutely specific for mature insulin, their usefulness would have been reduced rather than enhanced! Unfortunately, other diseases, including insulin resistance, require accurate measurements of the levels of mature insulin in the blood. Attempts to investigate insulin resistance using comparatively nonspecific immunoassays that also recognize unprocessed forms of the protein are likely to yield unreliable results.

The problem of antibody specificity has also arisen in the context of multiplex immunoassays (antibody arrays). This reflects the fact that most antibody arrays are currently used to detect particular, restricted classes of proteins, often cytokines or other secreted factors that are released into the serum or culture medium. Such antibodies have been developed especially for serum profiling and in many cases have not been checked for broader cross-reactivity, e.g., in cell lysates. In the few studies that have addressed this issue, the data suggest that up to 50% of antibodies used on chips cross-react with nontarget antigens. The proteins in a typical clinical sample cover a broad dynamic range, so antibodies with high affinity for a scarce target analyte and low cross-affinity for an abundant nontarget analyte might bind both equally well. This would provide a completely false indication of the relative abundances of the two analytes in the sample. It is therefore likely that many of the antibodies currently used for single-target immunoassays will be unsuitable for antibody arrays.

### **Monoclonal, Polyclonal, and Recombinant Antibodies**

Although the lack of specificity described above was at first thought to be confined to assays using polyclonal antibodies and would not occur with assays constructed using monoclonal antibodies, it is now quite clear that this was based on a misconception. The problem of cross-reactivity is not so much to do with the multiple antibody types present in polyclonal sera but instead reflects the conservation of epitopes between target and nontarget proteins, such as the processed and unprocessed forms of insulin. The great advantage of monoclonal antibodies is that, because they are produced from an immortal strain of cells rather than a single (mortal) animal, they can be characterized much more thoroughly than a polyclonal antibody. Also, from the point of view of a kit manufacturer, continuity of supply can be guaranteed.

Cross-reactivity can be reduced using the sandwich assay approach, because two noncompeting antibodies (i.e., antibodies recognizing different epitopes of the antigen) are required for each target protein. However, even this does not guarantee specificity. More recent approaches to antibody generation, such as phage display, can be used to circumvent some of the limitations of conventional hybridoma technology and select antibodies that show specificity for particular variants of a given protein. However, maximum specificity and sensitivity requires a combination of immunoassay and physical separation techniques, such as electrophoresis or liquid chromatography.

**Table 3** Protein-bound analytes of major clinical significance

Analyte	Binding protein	Factors influencing abundance of binding protein
Cortisol	Transcortin	Increased by estrogens, pregnancy
IGF-I, IGF-II	IGF-binding proteins (IGF-BPs)	Growth hormone increases IGF-BP 1 and 3 Insulin decreases IGF-BP 1
Insulin	Autoantibodies	Autoimmune disease
Testosterone	Sex hormone binding globulin	Estrogen, thyroxine and pregnancy increase, testosterone decreases
Thyroxine and T <sub>3</sub>	Prealbumin	Malnutrition decreases
	Thyroid binding globulin	Estrogens, pregnancy increases Adrogens, malnutrition decreases
Vitamin A	Retinol-binding protein	Zinc deficiency decreases

This approach has been used, for example, to measure tetrahydrocannabinol (the active ingredient of cannabis) in blood plasma in the presence of much higher concentrations of its inactive metabolites, and insulin in the presence of proinsulin and its split products.

### Standardization

It is an absolute requirement of all validated immunoassays, whether competitive or immunometric, that for accurate quantitative analysis the standard material used to calibrate the reaction is identical to the analyte. This may be difficult for several reasons, including the chirality of the analyte and its heterogeneity in terms of post-translational modification.

Chirality is generally only a problem in clinical applications when the assay involves a comparatively small molecule, such as a drug or a small synthetic peptide. Antibodies, like most biological reagents, exhibit 'handedness' or chiral specificity. Therefore, where the analyte occurs as a mixture of enantiomeric forms, only one enantiomer may bind to the antibody, or different enantiomers may bind with different affinities. The relevance of the standard depends on whether it is presented as a pure enantiomeric form, or as a mixture of enantiomers that reflects the composition of the analyte.

Where the analyte is a protein, variations in the type and amount of post-translational modification are important. Most proteins produced in mammalian cells are modified either by phosphorylation, glycosylation, or some other form of chemical adduct. In the case of phosphorylation, a protein may have several target sites for the addition of phosphate groups and may exist as a complex mixture of phosphoforms, not all of which will bind to the antibody with equal affinity. The situation with glycoproteins is even more complex, since there may be hundreds of different variants. In many cases, the protein used as a standard in immunoassays is a

recombinant protein produced in a heterologous expression system. It should be noted that mammalian proteins synthesized in bacteria are neither phosphorylated (at least not on the typical serine, threonine, and tyrosine residues) nor glycosylated. Additionally, the glycan structures produced in different expression systems are very diverse, and even mouse cells produce subtly different glycans to human ones. A further consequence of this diversity is that the results obtained using one manufacturer's antiserum, label, and standards are generally incompatible with those obtained using another's.

### Interference from Binding Proteins

Most clinical immunoassays require neither prior extraction nor purification of the sample containing the analyte before they are added to the reaction containing the appropriate amounts of high-affinity specific antibody and label. This is not the case, however, for analytes such as thyroxine or cortisol, which are tightly bound to highly avid binding proteins that compete with the antibody for both the analyte and the label. Some of the more important protein-bound analytes are shown in **Table 3**.

Similar constraints apply when the patient has developed antibodies of their own to the analyte, either as a result of autoimmune disease (e.g., in the case of thyroxine) or prior immunization (e.g., in the case of insulin or growth hormone). Under these circumstances, extraction of the sample prior to analysis is essential if reliable and accurate results are to be obtained.

### Introduction

National and transnational regulatory frames, improved awareness of health- and quality-related issues, and growing occurrence among the general population of adverse reactions toward some food components have increased the need for specific and sensitive methods capable of assessing specific food constituents, as well as additives, adulterants, and contaminants.

In many cases, only immunoassays are able to fulfill these requirements, and thus are gaining increased recognition as regular analytical methods in laboratories involved in food research or inspection. This trend is supported by a growing array of companies that supply the materials – and develop or perfect procedures – for this type of application. The increased diffusion of these techniques has also caused enzyme-based immunoassays to become the most popular methodology, in that it does not bring up all the regulatory issues and does not require the sizable investments associated with the use of radiochemicals. In this frame, enzyme-linked immunosorbent assays (ELISA) offer the advantage of being convenient, of being suitable for automated handling of a large number of samples, and of being relatively cheap.

From the standpoint of sample preparations, food-stuffs are much more complicated systems than clinical samples, which represent the other major area of application for the different techniques used in immunoassays. Food comes in many different physical forms, and very often it has undergone technological processes (physical, chemical, enzymatic,

alone or in combination) that may strongly affect the procedures to be developed for detection and/or recovery of a given analyte. This is especially true for proteins, whose structure (including epitopic regions or sequences) is highly sensitive to process-induced changes, which result in a modification of their immunoreactivity. In the case of proteins, changes may stem from process-induced cuts in the primary structure, from the introduction of nonphysiological amino acid through adduct formation, and from alteration in their high-order structures, which may affect their physical properties (such as solubility), as well as destroy conformational epitopes or hide sequential ones. In general terms, the processes used either by the food industry or in the preparation of meals at home may alter fundamental properties of the analytes, such as their solubility in a given extractant or their relationships to other food components.

Furthermore, analytes involved in food immunoassays are of extremely different chemical nature, and are present in a very broad range of concentrations. Whereas macromolecules (such as protein, enzymes, polysaccharides, and microbial cell-wall components) are generally present in the mg per kg range, environmental contaminants, residues from farming practices, antibiotics, toxins, and pathogens are often present at much lower concentration, as low as 0.1 µg per kg. Food analytes for which immunoassays have been developed and are commercially available are listed in Table 1.

### Identification and Quantification of Selected Proteins

Immunoassays are broadly used in food analysis for detection and quantification of small quantities of proteins in a given food for three main reasons.

### Introduction

National and transnational regulatory frames, improved awareness of health- and quality-related issues, and growing occurrence among the general population of adverse reactions toward some food components have increased the need for specific and sensitive methods capable of assessing specific food constituents, as well as additives, adulterants, and contaminants.

In many cases, only immunoassays are able to fulfill these requirements, and thus are gaining increased recognition as regular analytical methods in laboratories involved in food research or inspection. This trend is supported by a growing array of companies that supply the materials – and develop or perfect procedures – for this type of application. The increased diffusion of these techniques has also caused enzyme-based immunoassays to become the most popular methodology, in that it does not bring up all the regulatory issues and does not require the sizable investments associated with the use of radiochemicals. In this frame, enzyme-linked immunosorbent assays (ELISA) offer the advantage of being convenient, of being suitable for automated handling of a large number of samples, and of being relatively cheap.

From the standpoint of sample preparations, food-stuffs are much more complicated systems than clinical samples, which represent the other major area of application for the different techniques used in immunoassays. Food comes in many different physical forms, and very often it has undergone technological processes (physical, chemical, enzymatic,

alone or in combination) that may strongly affect the procedures to be developed for detection and/or recovery of a given analyte. This is especially true for proteins, whose structure (including epitopic regions or sequences) is highly sensitive to process-induced changes, which result in a modification of their immunoreactivity. In the case of proteins, changes may stem from process-induced cuts in the primary structure, from the introduction of nonphysiological amino acid through adduct formation, and from alteration in their high-order structures, which may affect their physical properties (such as solubility), as well as destroy conformational epitopes or hide sequential ones. In general terms, the processes used either by the food industry or in the preparation of meals at home may alter fundamental properties of the analytes, such as their solubility in a given extractant or their relationships to other food components.

Furthermore, analytes involved in food immunoassays are of extremely different chemical nature, and are present in a very broad range of concentrations. Whereas macromolecules (such as protein, enzymes, polysaccharides, and microbial cell-wall components) are generally present in the mg per kg range, environmental contaminants, residues from farming practices, antibiotics, toxins, and pathogens are often present at much lower concentration, as low as 0.1 µg per kg. Food analytes for which immunoassays have been developed and are commercially available are listed in Table 1.

### Identification and Quantification of Selected Proteins

Immunoassays are broadly used in food analysis for detection and quantification of small quantities of proteins in a given food for three main reasons.

**Table 1** Analytes detected and quantified in food immunoassays

<i>Role</i>	<i>Chemical nature</i>	<i>Categories or examples</i>
Quality markers	Proteins Amino acid derivatives	Naturally occurring, species-specific; process sensitive Formed in processing
Allergens	Proteins	Naturally occurring in: nuts, fruits, gluten, eggs, milk, etc.
Additives	Proteins Polysaccharides	Enzymes used for processing purposes Gums
Adulterants	Proteins	Proteins from cheaper sources
Risk factors	Proteins	Spinal and CNS tissue
Residues	Small molecules	Antibiotics, hormones, anabolic agents, pesticides, drugs
Contaminants	Whole cells Small molecules	Pathogens Bacterial and fungal toxins

The first is to detect the possible use of cheap ingredients to supplement high-quality ones. Typical examples include: (1) the addition to beef and pork of cheaper meats (such as sheep, goat, horse, rabbit, or kangaroo), or of soyabean proteins; (2) the addition of cow's milk to sheep's and goat's milk and cheese; (3) the replacement of malted barley by rice or maize; and (4) the replacement of hazelnuts with various cheaper nuts.

The second is the detection and quantification of proteins that are involved in intolerance or in allergic response to some foods by sensitive individuals. Typical examples include the detection of: (1) gluten in food to be consumed by coeliac individuals; (2) milk allergens such as caseins or beta-lactoglobulin; (3) egg protein allergens; and (4) allergens of vegetable origin, such as those found in nuts, almonds, beans, and in many fruits.

The third is the detection of tissue-specific and/or species-specific antigens, as in the assays developed to detect cerebral or spinal tissues that may be present in food and feed and that may be linked to transmissible encephalopathies.

In all the cases, the main problem with protein assay in foodstuff is the different sensitivity of the various proteins to the large variety of processes used for food preparation/preservation. For example, all heat treatments affect the high-order structure in proteins (and therefore conformational epitopes), and quite often result in protein insolubilization, thus making it difficult to recover the target analyte from the processed food.

These difficulties have been circumvented by two different approaches. The first relies on the choice of heat-resistant protein antigens as the analyte. These antigens may be represented by carefully selected intact proteins (as exemplified by the choice of  $\omega$ -gliadins for gluten detection), or by antigenic peptide fragments that are not as sensitive to treatments as the intact protein they come from. The second approach to the detection/quantification of process-sensitive proteins calls for the solubilization of the

denatured protein analyte by suitable combinations of solubilizing agents (typically, by mixtures of chaotropes such as urea and guanidine, detergents, and disulfide-reducing agents). In this case, it is worth to remember that a protein denatured under similar conditions is best suited as an antigen when developing and isolating the antibodies to be used subsequently for analytical purposes.

Besides the analytical uses discussed above, protein immunoassays also may be useful for assessing the suitability of raw materials for production of a given food, and for controlling different stages of processing. For instance, epitope-specific monoclonal antibodies have been used for studying residual protein components in the course of brewing, or for distinguishing between normal and heat-damaged gums. Process-induced disappearance of milk proteins and formation of specific peptides during cheese ripening have also been assessed by immunochemical techniques.

Protein immunochemistry has been used also to verify the presence, the nature, and the origin of a number of enzymes currently used in the food industry, since immunochemical techniques allow detection of these additions even after the original activity of the enzyme is lost upon stabilization of the product (e.g., by heat treatment or by addition of enzyme-inactivating agents), or when measurement of the enzyme activity does not provide hints as for its origin (as is the case for many renneting enzymes used in the dairy industry).

In many cases, for the purpose of protein identification, immunochemical techniques have been combined with separation methods and with other methodologies. A good example of a combined procedure is the identification of the protease-resistant pathological form of the prion protein, in which the products of specific proteolysis of the whole tissue are first separated by electrophoresis, and identified by specific monoclonal antibodies after transfer (blotting) to a suitable membrane. Another common application of immunoblotting techniques is the identification of the food proteins (and of peptides

derived from their hydrolysis) that may be responsible of the allergic response in sensitive individuals. In this case, blotted proteins/peptides may be tested for immunoreactivity toward the patient's serum, thus providing information as for the nature of the allergens that have sensitized a given individual.

## Microorganisms and Microorganism-Derived Toxins

Modern, sensitive immunoassays based on an ELISA format are gradually replacing several of the serological methods (agglutination, precipitation) widely applied in food microbiology for the differentiation of bacterial and fungal strains. Most immunoassays are based on the occurrence of specific antigens in cell membranes or in the cytoplasm, although in some cases extracellular polysaccharides, toxins, or enzymes are detected. Some microbial species and strains for which immunoassays have been developed and for which analytical kits are commercially available are listed in **Table 2**, which also provides information as for the analysis format.

In the field of food microbiology, immunochemical methods are advantageous with respect to microbiological methods in terms of labor and time, in particular for those species and strains whose isolation and identification call for lengthy and cumbersome procedures. Immunochemical procedures allow cutting down substantially on these requirements, by following different strategies.

In some cases, as for *Campylobacter*, a one-broth, two-step enrichment protocol is immediately followed by a rapid immunoassay. In other cases, as for

*Listeria*, after a preliminary enrichment step, a quick immunoassay step is used to establish possible positives, in which the presence of *Listeria* will be confirmed through microbiological tests. In the case of *Salmonella*, a preliminary enrichment step is followed by growth of the bacteria in a medium capable of stimulating production of the somatic and flagellar proteins that represent the specific reactive antigens detectable in subsequent immunoassay.

When the food contaminant acts through the production of bacterial toxins, which may be heat-resistant and be present also when no viable cells are present, antibodies may be raised against the toxin itself, or against different subsets of toxin. Such approaches have been used for developing immunoassays for the verocytotoxin producing serotypes (VTEC) of the *Escherichia* genus that are well known causes of diarrhoea in humans, and include the serotype O157, currently the most prominent food-borne agent connected to enterohemorrhagic *Escherichia coli* (EHEC) infections. A similar case is the enterotoxins produced by certain strains of *Staphylococcus aureus*. Staphylococcal enterotoxins (SET) have almost total resistance to dehydration, proteolytic enzymes, and heat treatment. The traditional methods used to detect SET are costly and lack the level of sensitivity required for industrial use. Available tests employ monoclonal antibodies that react specifically with food-borne SET A, B, C, D, and E. Compared with the microslide double-diffusion reference method, which is laborious, slow, and inadequate in detecting low levels of contamination, ELISA-format kits are simple, rapid, and highly sensitive, with detection limits of less than 1 ng per g or ml<sup>-1</sup>. Results are available within 3 h, including sample preparation.

Often, commercial kits aimed at the detection of food pathogens are available in both 'card' and 'plate' formats, with the card format being suited for the purpose of rapid, preliminary screening, and the plate format – which typically requires skilled operators and a minimum of lab equipment – being more suited whenever reliable results are required.

As made evident in **Table 2**, immunoassays are also in routine use for analysis of mycotoxins, a group including the most dangerous and analytically elusive food-related toxins. In spite of the small structural differences within specific groups of mycotoxins (aflatoxins, ochratoxins, trichothecenes), assay specificity toward the other mycotoxin groups is always total. Determination of AFB<sub>1</sub>, toxin T-2, and ochratoxin A in a single extract from barley grains has been reported. Mycotoxins may be determined in crude extracts of various foodstuffs at concentration over 20 ng per kg. This detection limit can

**Table 2** Availability of commercial immunochemical kits for microorganism and toxins

Microorganism/toxin detected	Food analyzed	Assay format
<i>Salmonella</i>	Various foods	Card, ELISA
<i>Listeria</i>	Milk, cheese, meat	ELISA
<i>E. coli</i> O157	Meat products	Card, ELISA
<i>Clostridium tyrobutyricum</i>	Milk	ELISA
<i>Staphylococcus aureus</i>	Meat products, beans	Tube, ELISA
<i>Campylobacter</i>	Chicken products	ELISA
Aflatoxin M1	Milk, cheese	ELISA
Aflatoxin B1	Cereals, cocoa, peanuts	ELISA
Zearalenone	Maize, wheat, milk	ELISA
Ochratoxin A	Cereals, feed	ELISA
Deoxynivalenol	Cereals, beer	ELISA
Seaweed toxins	Fish	ELISA
Total aflatoxins	Cereals	Card

be further improved by fast clean-up of the extract on solid-phase extraction cartridges.

In the frame of mycotoxin analysis, it is worth remembering that immunoaffinity columns are used for enrichment of samples to be analyzed by solution chemistry or by liquid chromatography. The use of immunoaffinity in this case allows a one-step removal of possible interfering agents from the sample.

## Residues and Contaminants

The residues of many contaminant compounds in food are present at extremely low concentrations (0.01–100 µg per kg). Preliminary extraction and purification steps are often necessary before measuring such low concentrations, calling for specialized laboratories, expensive procedures, and high standards of expertise. Furthermore, traditional methods based on liquid or gas chromatography (coupled to mass spectrometry when necessary) do not easily accommodate a large number of samples.

The high sensitivity and specificity of immunoassays make it possible to minimize the sample size and the volume of extracting solvents, and often allows to eliminate time-consuming purification procedures altogether. However, in the particular case of small molecules with similar chemical properties, immunochemical cross-reactivity may impair to some extent the selectivity of the assay, making it most suitable for screening purposes rather than for quantification of a single compound, as will be discussed in what follows. On the other hand, this cross-selectivity makes immunoassays the best choice when applied to the detection of a family of analytes for semiquantitative screening of a large number of samples or for monitoring a process or a process ingredient in continuous-flow fashion.

Although immunoassays have been developed at the laboratory scale for a broad variety of possible food contaminants and of natural food components whose presence may affect the sensory or nutritional properties of a given food, we will discuss in what follows only those applications that have already gained acceptance in the analytical laboratory, and for which commercial kits are available, as reported in Table 3.

Antibiotics and other drugs have been applied to farm animals ranging from catfish to honeybees, for the prevention or treatment of diseases, elimination of parasites, or growth promotion. Transfer of these substances to humans through the food chain is a serious concern, and antibiotic levels in various foods are often the subject of strict regulation. Immunoassays developed for these molecules are highly

**Table 3** Availability of commercial ELISA kits for residues

<i>Residue</i>	<i>Analyzed material</i>
<i>Antibiotics</i>	
Chloramphenicol	Meat, eggs
Sulfamethazine	Meat, milk
Streptomycin	Meat, milk
Tetracycline	Meat, milk, eggs
Nitrofurantoin	Meat, milk
Sulphathiazole	Honey
<i>Pesticides</i>	
Triazine	Maize
Isoproturon	Barley, wheat
Alachlor	Maize
<i>Hormones and <math>\beta</math>-agonists</i>	
Clenbuterol	Meat, liver, powder milk
Acetylgestagene	Fat
Melengestrol acetate	Meat
17 $\beta$ -Estradiol	Plasma
Testosterone	Plasma
Ethinylestradiol	Plasma, urine
Trenbolone	Meat
Zeranol	Urine
Methyltestosterone	Urine
Nortestosterone	Meat
Dexamethasone	Meat, milk
Salbutamol	Meat, liver, powder milk

sensitive and specific, and often require only a minimal clean-up after the initial high-efficiency extraction from the tissue or food.

The cheap synthetic anabolic agents used to increase the efficiency of meat production are another category of contaminants that has harmful effects on the human consumer, and therefore are banned in almost all countries. Successful analytical procedures for hormones and  $\beta$ -agonists combine liquid chromatography separation with sensitive quantification by immunochemistry. Since often these analyses are carried out in large and dedicated institutional laboratories, this is one case in which the radioimmunological methods typical of the clinical lab (such as radioimmunoassay and several types of surface-based immunochemistry) are still enjoying great popularity. This attitude also reflects in the sampling procedure, which often involves taking samples of biological fluids from live animals prior to slaughtering.

In recent years, immunoassays for pesticides, phyto-pharmaceuticals, and industrial pollutants (polychlorinated biphenyls, dioxins, etc.) have become accepted as methods that complement traditional analytical procedures also in the field of food analysis (including drinking water). In the case of pesticides, both quantitative and semiquantitative kits are available. Cross-reactivity may occur – although with different efficiency – between an antibody raised against a protein conjugate of a given compound, and structurally

similar compounds in the same class. This can be exploited to provide a very fast estimate of total contaminants (within a given class) in a food sample.

### **Practical Considerations, Assessment of Assay Performance, and Comparison with Alternative Procedures**

Rapid screening tests such as the so-called 'test-tube', 'spot', and 'dipstick' tests available for semiquantitative analysis of food have placed immunochemical detection within the reach of nontrained operators aiming at a coarse first look at foods to be used for home consumption.

Although the procedures involved in performing immunoanalytical procedures seem to be simple, and the kits available for immunoassay in food have greatly increased their popularity, there are a number of caveats that must be considered to avoid mistakes, in particular when quantitative analysis is required. In this case, attention should be paid to product shelf-life, to running proper standards for each set of measurements, to strict adherence to the recommended procedures for sample preparation, and to proper dilution of the sample so that the analyte concentration falls within the range of the calibration curve. Given the typical logarithmic response of all ELISA tests, and the margin of error intrinsic to these determinations, performance of measurements at multiple dilutions of the same sample is highly recommended, also in routine work.

Issues related to sampling procedures, efficiency of extraction, cross-reactivity, and analyte recovery may often require the use of internal standards. The analyst should also be aware that interference – often unexpected – from other food components is also common in the complex matrices that characterize foods. For this reason, a protocol devised for a particular food (e.g., cow's milk) cannot be transferred to an apparently similar food (e.g., sheep's or goat's milk) without suitable experimentation and adequate validation. Removal of interfering materials – once their nature is known – may also be necessary in some cases, and may call for specific procedures, such as addition of precipitating agents, ultrafiltration, dialysis, etc. The easiest way to detect interference, if suspected, is to prepare analyte standards in buffer and in the food matrix at concentrations compatible with the assay. Assays performed with both sets of standards should produce identical curves in the absence of interference. The effects of these treatments on the analyte itself will have to be assessed by experiment.

Also, comparison of results obtained with different commercial kits is often difficult, in what they may

differ in the nature of the target antigen, in procedure used for sample preparation, and in the properties (specificity, titer) of the particular antibody used for the assay itself. Cross-reactivity is often an issue, in particular when the supplier of the antibodies does not specify whether it has been tested on a specific material.

In a still growing number of reports, immunochemical methods have been compared with conventional analytical methods, and extremely good agreement has been found, in particular when researchers were familiar with all the methods involved. In most cases, the advantages of immunochemical methods in food analysis (sensitivity, specificity, cost, ease of use, rapidity, ease of automation) outweigh the intrinsic disadvantages discussed above. In this framework it has to be noted that traditional analytical procedures suffer from the same limitations (matrix effects, interference, recovery difficulties, etc.) when applied to food systems, and that immunochemical methods often offer analytical possibilities that just are not attainable with conventional methods. The major limitation of immunochemical methods in food analysis, as of today, is that they are not readily applicable to simultaneous multianalyte analysis. On the other hand, they likely are the most appropriate choice whenever screening a large number of samples for one – or a few – known analytes.

When compared to other methods based on recognition of foreign biological matter in food, immunochemical methods still appear to have some important advantages even on high-sensitivity, polymerase chain reaction (PCR)-based analytical techniques, including quantitative PCR methods. First and foremost, immunochemical methods are aimed at the detection of a specific protein in a given food, rather than at the presence of residual DNA from a given organism. This is of paramount importance in all cases when the protein itself (and not other biological material from the same organism) is somewhat deleterious for the quality/safety of a given food. In other words, taking gluten as an example, food that tests gliadin-free by properly performed immunochemical analysis may be consumed safely by a gliadin-sensitive individual, even if it proves to contain residual wheat DNA. Also, the application of PCR-based techniques to food analysis suffers from recovery and interference problems not smaller than those encountered when immunochemical techniques are used.

## Introduction

The terms forensic medicine, forensic science, and forensic pathology are often confused. However, forensic medicine or science in the broad sense can be classified into three main fields: forensic pathology, forensic toxicology, and forensic biology. Forensic pathology deals with the issues diagnosed at forensic (and administrative) autopsy. In forensic toxicology, all problems in relation to substances with pharmacological/poisonous effects on humans are investigated. Forensic biology is the field in which genetic markers or proteins are investigated in cases of stain analysis, autopsy of unidentified bodies, and paternity tests.

Immunoassay commonly means a method for quantitative analysis of a substance using immunoreactions. However, the original meaning of the word 'assay' is not restricted to quantitative analysis and enzyme-linked immunosorbent assay (ELISA) has been developed in the area of histology as a qualitative investigation method to identify the existence/localization of antigens (immunohistochemistry). Besides, forensic analysis frequently requires a qualitative judgment and it is often achieved by examination using immunoreactions. Therefore, in this article we deal with the word 'immunoassay' in the broad sense including both quantitative and qualitative/semiquantitative analyses using immunoreactions.

## Immunoassays in Forensic Pathology

### General Aspects

Forensic pathology involves the diagnosis of cause of death, determination of time of death, estimation of

degree and properties of injuries, etc. Analysis of morphological changes and pathogenesis induced by external factors or internal diseases are also important issues in this field. However, it is sometimes very difficult to solve such problems only by autopsy findings and attempts have been made to develop helpful examinations for forensic pathological diagnosis. For this purpose, proteins/hormones as clinically useful markers have also been utilized in this field; many authors have determined quantitatively such substances in autopsy materials using commercially available immunoassay kits and have discussed the results obtained.

We must pay attention, however, to the fact that the nature of autopsy materials is quite different from those used in clinical medicine. A blood sample obtained at autopsy is sometimes extremely hemolyzed and its supernatant is neither serum nor plasma, because postmortem intensive fibrinolysis following blood coagulation had already occurred in the corpse at autopsy. Body fluids other than blood/urine or extract of tissue-homogenate cannot normally be considered for clinical use. Most important is that many kinds of proteins are contained in extremely large amounts in autopsy material, which may be available for forensic examination and can by no means be expected to be used in clinical laboratory medicine. Such samples can cause very strong suppression of necessary immunoreactions in the assay system established for clinical use. This means that the values determined may not be comparable if different immunoassay kits are used, even if the same protein is assayed. Besides, the value for a postmortem sample may be false if its assay is completely carried out in a clinical laboratory where no one knows about the particular nature of the autopsy material. This is the probable reason that some conclusions obtained from different studies on the same substance are sometimes contradictory. In spite of such circumstances, the attempted quantitative analysis has been reported as useful in most of the earlier studies.

## Introduction

The terms forensic medicine, forensic science, and forensic pathology are often confused. However, forensic medicine or science in the broad sense can be classified into three main fields: forensic pathology, forensic toxicology, and forensic biology. Forensic pathology deals with the issues diagnosed at forensic (and administrative) autopsy. In forensic toxicology, all problems in relation to substances with pharmacological/poisonous effects on humans are investigated. Forensic biology is the field in which genetic markers or proteins are investigated in cases of stain analysis, autopsy of unidentified bodies, and paternity tests.

Immunoassay commonly means a method for quantitative analysis of a substance using immunoreactions. However, the original meaning of the word 'assay' is not restricted to quantitative analysis and enzyme-linked immunosorbent assay (ELISA) has been developed in the area of histology as a qualitative investigation method to identify the existence/localization of antigens (immunohistochemistry). Besides, forensic analysis frequently requires a qualitative judgment and it is often achieved by examination using immunoreactions. Therefore, in this article we deal with the word 'immunoassay' in the broad sense including both quantitative and qualitative/semiquantitative analyses using immunoreactions.

## Immunoassays in Forensic Pathology

### General Aspects

Forensic pathology involves the diagnosis of cause of death, determination of time of death, estimation of

degree and properties of injuries, etc. Analysis of morphological changes and pathogenesis induced by external factors or internal diseases are also important issues in this field. However, it is sometimes very difficult to solve such problems only by autopsy findings and attempts have been made to develop helpful examinations for forensic pathological diagnosis. For this purpose, proteins/hormones as clinically useful markers have also been utilized in this field; many authors have determined quantitatively such substances in autopsy materials using commercially available immunoassay kits and have discussed the results obtained.

We must pay attention, however, to the fact that the nature of autopsy materials is quite different from those used in clinical medicine. A blood sample obtained at autopsy is sometimes extremely hemolyzed and its supernatant is neither serum nor plasma, because postmortem intensive fibrinolysis following blood coagulation had already occurred in the corpse at autopsy. Body fluids other than blood/urine or extract of tissue-homogenate cannot normally be considered for clinical use. Most important is that many kinds of proteins are contained in extremely large amounts in autopsy material, which may be available for forensic examination and can by no means be expected to be used in clinical laboratory medicine. Such samples can cause very strong suppression of necessary immunoreactions in the assay system established for clinical use. This means that the values determined may not be comparable if different immunoassay kits are used, even if the same protein is assayed. Besides, the value for a postmortem sample may be false if its assay is completely carried out in a clinical laboratory where no one knows about the particular nature of the autopsy material. This is the probable reason that some conclusions obtained from different studies on the same substance are sometimes contradictory. In spite of such circumstances, the attempted quantitative analysis has been reported as useful in most of the earlier studies.

Many morphological studies have also been reported in this field. In these studies, several antigens are stained by immunohistochemistry and the diagnostic value of the findings is evaluated according to issues such as cause of death, nature of injury, and postmortem interval. In these studies, commercially available antibodies have been used.

The situation stated above means that the immunoassays of convenient markers are helpful for forensic pathological diagnosis. However, almost all investigations ended with a particular approach or report, and unfortunately none of them has become a routine procedure in forensic autopsy in all institutes. In the following section, we introduce the hitherto reported approaches to forensic pathological diagnosis using immunoassays. Some of them are introduced in **Table 1**.

### Practical Applications

The main issue in which qualitative immunoassay is used in forensic pathology is diagnosing the cause of death. The most frequent approach is to diagnose sudden cardiac death (SCD), myocardial infarction, and ischemic damage of the myocardium by determining the proteins in the myocardium, such as myosin, myoglobin, troponins, in blood, and/or pericardial fluid by immunoassay. The determination of the content, not activity, of creatine kinase-MB isozyme by immunoassay has also been attempted. Other approaches analyzing the relationship between the concentration of proteins in blood and cause and/or pathogenesis of death were: asphyxia by neck compression and thyroglobulin, drowning and SP-A or -D (pulmonary surfactant), electric death and

myoglobin, and so on. Some authors took note not of a special cause of death but of a special substance, e.g., SP-A in blood, CRP in blood, myoglobin in urine, and analyzed the relationship between these substances and causes of death in general.

Quantitative/semiquantitative immunoassays are applied to the analysis of the nature of an injury. The estimation of the grade and analysis of pathogenesis of brain injury were attempted by determining neuron-specific enolase (NSE) and tumor necrosis factor (TNF)- $\alpha$  in cerebrospinal fluid. Concerning the skin wound, it has been said that the fibrin-fibrinogen degradation product (FDP)-D dimer can be used as a marker of vital reaction and that the content of interleukins (IL)-6, IL-1 $\beta$ , and TNF- $\alpha$  in the tissue is useful for estimating wound age. For the discrimination of subcutaneous hemorrhage from exuded hemoglobin due to putrefaction, determination of glycophorin-A has been recommended.

Some examples of other studies using quantitative immunoassays in forensic pathology are: vascular endothelial growth factor (VEGF) contents in brain and some other organs for the diagnosis of postmortem interval/time of death, melatonin concentrations in blood, urine, and pineal gland for the same purpose, and serum triptase concentration for the diagnosis of heroin-related death.

Immunohistochemistry is the most widely used technique for qualitative immunoassay in the field of forensic pathology. The frequent approach is to diagnose cause of death, especially SCD. C5b-9 (complement complex), fibronectin, cardiac troponin, and other proteins are stained for this purpose and the usefulness of their staining has been discussed. Many

**Table 1** Approaches to forensic pathological diagnosis using immunoassay

Analyzed/identified issue	Material	Type of assay	Representative antigen(s) noticed
Diagnosis of cause of death			
Sudden cardiac death	Blood, pericardial fluid	Qt	Myosin, troponin, myoglobin
	Heart	IH	C5b-9, fibronectin, troponin
Drowning	Blood	Qt	Pulmonary surfactant
	Lung	IH	Pulmonary surfactant
Asphyxia by neck compression	Blood	Qt	Thyroglobulin
	Soft tissue of the neck	IH	Myoglobin, fibronectin, glycophorin-A
Sudden infantile death	Lung or other organs	IH	Milk components, S-100, insulin
Diagnosis of nature of injury			
Wound age	Skin	IH	Collagen, fibronectine, cytokeratin, interleukins
	Brain	IH	GFAP, thrombomodulin
Vital reaction	Skin	Qt	FDP-D dimer
	Hematoma	IH	Glycophorin-A, CD62
Diagnosis of postmortem interval	Some organs	Qt	VEGF
	Pancreas	IH	Insulin, glucagon
	Thyroid gland	IH	Thyroglobulin
	Heart	IH	Myoglobin

Qt, quantitative analysis; IH, immunohistochemistry.

studies on sudden infant death syndrome and infantile sudden death using immunostaining have also been reported. In these studies, S-100 protein, hypothalamic hormones, insulin, glial fibrillary acidic protein (GFAP), calcitonin, CD 4, SP-A, and other proteins/hormones were stained in various organs/tissues and the significance of such staining was evaluated from the forensic pathological viewpoint. An interesting approach to diagnose the cause of infantile sudden death was the immunostaining of the components of human and cow milk in the lung. Other applications of immunohistochemistry to the diagnosis of cause of death were in the investigations of the relationship between SP-A in lung and drowning, adult respiratory distress syndrome, death due to fire; pulmonary mast cell triptase and amniotic fluid embolism; glycophorin-A, myoglobin, fibronectin in muscle and asphyxia by neck compression, and so on.

There have also been many immunohistochemical studies on injury. For the estimation of the age of a skin wound, numerous substances were stained and their usefulness discussed. The stained proteins were: fibronectin, collagen, laminin, cytokeratin, CD54, IL-6, IL-1 $\beta$ , and TNF- $\alpha$ . In order to confirm the vital reaction in a skin wound, immunostaining of  $\alpha$ 1-antichymotrypsin,  $\alpha$ 2-microglobulin, fibronectin, and some other substance was reported to be useful. In the analysis of brain injury using immunostaining, the following combinations of protein(s) have been described to be useful: NSE for demonstrating vital reaction and diffuse axonal injury; Collagen IV, thrombomodulin, GFAP, and some other proteins for the estimation of the age of the wound; and HSP (heat shock protein) 70, GFAP, and some other proteins for analysis of hypoxic/ischemic brain damage. For the discrimination of antemortem bleeding from postmortem hemoglobin diffusion, immunostaining of glycophorin-A and its quantitation are useful. In another report, it has been described that immunoelectronmicroscopical staining of CD 62 and other antigens on platelets could distinguish intravital hematoma from postmortem hematoma.

Other analyses using qualitative immunoassays in forensic pathology are as follows: insulin and glucagon in pancreas, myoglobin in heart, thyroglobulin in thyroid gland, S-100, cytokeratin, and other substances in sweat gland, and other attempts for diagnosing the postmortem interval/time of death, thyrosin-phosphorylated proteins in thymus for demonstrating child abuse,  $\beta$ -amyloid, GFAP, and Tau-protein in brain for postmortem diagnosis of Alzheimer's disease, leukotoxin in lung for analyzing pathogenesis of paraquat poisoning/hyperoxic condition.

There have been some approaches in the border area between pathology and biology or toxicology.

An example is the method for identifying the used weapon in the case of injury/homicide by detecting the organ-specific antigen. If the specific antigen of the injured organ is detected from the stain on the suspected weapon, it can be identified as the weapon used in the incident. Though identifying/presuming the used weapon is one of the essential issues in forensic pathological diagnosis, stain analysis belongs principally to forensic biology (see the section 'Immunoassays in forensic biology – practical applications'). Another example is the analysis of cause and/or pathogenesis of death in a case of poisoning or death under the effect of drug/poison. Though this kind of analysis is an issue of diagnosis required at forensic autopsy, it also depends on forensic toxicological analysis: drug-related pathological changes, including immunohistochemical detection of drug/poison distributed in the body, and the quantitation of drug/poison in autopsy materials.

## Immunoassays in Forensic Biology

### General Aspects

Forensic biology has anthropological and genetic aspects. Analysis of genetic markers is indispensable for a paternity test and for the personal identification of stains or unidentified bodies. In these circumstances, examination of genetic markers is the most frequent and important business in forensic biological practice.

Up to the middle or end of the 1990s, blood types were examined using immunoreactions as important genetic markers. Many immunoassays have been developed to determine their phenotypes. The status of immunoassays in this field, however, has changed greatly in recent years. With the development of DNA technology, blood cell/serum protein types as the tool for personal identification/paternity test were substituted by STRs (short tandem repeats polymorphisms)/SNPs (single nucleotide polymorphisms) and the necessity of examining classical genetic markers was remarkably reduced. Nevertheless, immunoassay will still be necessary in forensic biology in the future, because some examinations required in this field cannot be established in DNA analysis (e.g., identification of semen).

Some commercially available immunoassay kits are applied to the analysis in forensic biology. Most of them are for qualitative/semiquantitative analysis. Although they are manufactured for clinical purposes and materials, they are also useful for forensic biological analysis with different purposes and materials. For example, an immunoassay kit for detecting prostate-specific antigen (PSA) in serum as a marker of prostate cancer is also applicable for

identifying semen using the extract obtained from a suspected dried body fluid stain (see below).

Many in-house developed ELISAs for the investigation of special issues have also been reported. They are not distributed in the market, but are worth being referred to when the same or similar investigation is required.

### Practical Applications

In the field of forensic biology, many kinds of immunoassays have been used for the examination of blood groups. A hemagglutination test using antisera is the classical method for determining blood cell types. HLA types have been determined using complement-fixation test. Some serum protein polymorphism has been examined using immunoblotting or immunofixation following isoelectric focusing.

These examinations of blood types were substituted for DNA analyses, especially STRs and SNPs. Because STRs/SNPs are much more polymorphic than the classical blood types, they have a great advantage in forensic biological practice. Besides, the polymerase chain reaction used for DNA analysis is very sensitive. Blood group determination, however, may be required in cases other than personal identification/paternity test: for example, in the case of incompatible blood transfusion. An absorption test of saliva can contribute to identifying the blood group of the recipient. The ABO blood group of the recipient may be identified in a short time if the distinct mosaic pattern with both agglutinated and nonagglutinated red blood cells is observed by a hemagglutination test. Though immunostaining of ABO blood group antigen using autopsy material is also useful for this purpose, it is now being substituted by DNA analysis.

Absorption and absorption-elution tests are the conventional methods used for determining ABO blood groups from stains. Immunohistochemistry can be applied to some stains and autopsy material. An absorption test on a body fluid stain can identify a secretor/nonsecretor. Many ELISAs to detect or quantify ABO/Lewis blood group antigen have also been reported. Although ELISAs had satisfactory specificity and sensitivity, they were not substituted for the absorption/absorption-elution tests, and ABO blood grouping by DNA analysis is now becoming a routinely used method. ELISAs using monoclonal antibodies, however, may still be useful, because some of them can determine the ABO blood group of a specific component in a mixed stain, e.g., ABO blood grouping of vaginal secretion mixed with semen.

Immunoassays have also been applied to species identification of stains. A precipitation test of the extract of the suspected stain against anti-human

serum or anti-human IgG (immunoglobulin G) is a classical method used for this purpose. Immunological detection of human Hb (hemoglobin) is now a popular method for species identification of bloodstains. This method has the advantage of not only identifying human origin but also confirming blood at the same time, compared with the methods for detecting other human components. Recently, commercially available immunoassay kits for clinical laboratory investigation to detect occult blood in feces have been applied to forensic human identification of bloodstains, because the antibodies used can reveal excellent specificity for humans. Since the last decade a highly sensitive immunochromatography device has been available. It is useful for species identification of stains from body fluids other than blood if they have only a minute contamination of Hb. However, very highly sensitive methods using DNA analysis have also been developed for this purpose.

We must note that some kinds of examinations in forensic biological practice cannot be established in DNA analysis and require immunological analysis. Identification of semen is one of the typical and important issues from this viewpoint. PSA is a well-known semen-specific substance and its detection by ELISA is the most common method for identifying semen from body fluid stain/vaginal content. Since it is an important clinical marker for prostate carcinoma, devices for detecting serum PSA using immunochromatography are marketed worldwide. Although the prepared sample is not serum for forensic biological examination, such a device is useful for detecting/identifying semen in the case of sexual assault. Gamma-seminoprotein is also a good marker for this purpose and it is said to be the same substance as PSA. ELISAs for  $\beta$ -microseminoprotein, semenogelin, and other substances were developed for identification of semen.

In bloodstain analysis, there are also some problems for which DNA analysis can give no solution. For example, in the case of murder/injury of a woman in menstruation, the offender sometimes claims that the bloodstain at the scene has originated from the blood of menstruation. In such cases the immunological determination of FDP is a useful means, because it is profusely contained in menstruation blood. There are some more examples in which immunoassay can be a useful tool for analysis. By detection of human chorionic gonadotropin (hCG) the blood of a pregnant woman can be identified, and determination of myoglobin, which is very much contained in the blood of a corpse, is useful for discrimination of antemortem and postmortem blood.

Identification of injured organ/tissue from bloodstain also requires immunological analysis, and ELISAs for the following proteins have been developed: S-100

**Table 2** Forensic biological analysis requiring immunoassay

<i>Material</i>	<i>Analyzed/identified issue</i>	<i>Representative antigen(s) noticed</i>
Bloodstain	Blood of pregnant woman	HCG
	Menstrual blood	FDP
	Postmortem blood	Myoglobin
	Injury of skeletal muscle	$\beta$ -enolase
	Injury of brain	S-100 protein
Body fluid stain/ vaginal content	Injury of liver	Liver-specific antigen
	Semen	PSA, $\gamma$ -Sm, semenogelin
Body fluid stain/ tissue fragment	Human origin	Human Hb, human IgG
Tissue fragment	Brain	Myosin, neurofilament
	Skin	Squamous cell carcinoma-related antigen
	Skeletal muscle	Myoglobin

protein (specific for brain),  $\beta$ -enolase (specific for skeletal muscle), elastase III (specific for pancreas), Tamm–Horsfall protein (specific for kidney). Liver-specific antigen was originally isolated and an ELISA of this protein was developed for the investigation of liver injury. Identification of organ/tissue itself from the fragment left at the scene is also an important issue in forensic stain analysis and some ELISAs have been reported: myosin or neurofilament for identifying brain tissue, myoglobin for identifying skeletal muscle, and squamous cell carcinoma-related antigen for identifying skin. Some ELISAs for organ/tissue-specific substances reveal a good specificity for humans at the same time. Representative analyses requiring immunoassay in forensic biology are shown in Table 2.

## Immunoassays in Forensic Toxicology

### General Aspects

Forensic toxicology refers to the broad field in which immunoassays are routinely used in forensic medicine/science. Determination of substances with pharmacological or poisonous effects on humans in autopsy materials plays a very important role in forensic toxicological practice, and detecting/determining drugs of abuse in urine/blood of living subjects is frequently required in this field. In these circumstances, many kinds of immunoassays for drugs have been developed, and they are marketed for practical use in forensic and clinical toxicology. Some immunoassays are also used to detect common drugs of abuse in extracts from hair, which has a large window for monitoring past drug history.

When detailed qualitative and precise quantitative analyses for drugs are required, we must choose instrument-based testing without immunoreactions, because the latter cannot discriminate the parent drugs from its metabolites/derivatives and chemicals that have similar structures. For example, putrefactive amines, such as phenethylamine, frequently give false positive results for amphetamines; dihydrocodeine gives positive results for opiates. However, immunoassay kits for chemical compounds are still useful, especially in screening.

The status of immunoassays in forensic toxicology is different from that in forensic pathology and biology. In the latter fields, analyses by immunoassays are tools for diagnoses, and to determine the target substance is not the final purpose of analysis. For example, a precipitation test for human IgG is a method for forensic species identification, but the essential purpose is not to detect IgG itself, but to identify its human origin, and there may be another more useful immunoassay for a new substance such as human Hb (see the section 'Immunoassays in forensic biology' above). On the contrary, immunoassay is itself the purpose in forensic toxicology. Immunoassays have been developed and investigated as methodology in this field. In the following section, we describe the present situation of immunoassays distributed in the market for forensic or clinical toxicology, and comment on their characteristics and principles. Immunohistochemistry in toxicology is briefly described in the section 'Immunoassays in forensic pathology'.

### Practical Applications

Immunoassays are used in forensic toxicology for routine screening and quantifying compounds. They have excellent sensitivity and specificity, and can be completed in a short period. Many immunoassays are available for testing common poisons in both urine and serum. The most common immunoassays used in forensic toxicology are: RIA (radioimmunoassay), EMIT<sup>®</sup> (enzyme-multiplied immunoassay technique, Behring Diagnostics), FPIA (fluorescence polarization immunoassay), CEDIA<sup>®</sup> (cloned enzyme donor immunoassay, Roche Diagnostics/Boehringer Mannheim Corporation), KIMS<sup>®</sup> (kinetic interaction of microparticles in solution, Roche Diagnostic Systems), and ELISA. The most commonly measured substances are amphetamines, barbiturates, benzodiazepines, cannabinoids, cocaine, methadone, opiates, phencyclidine, propoxyphene, and tricyclic antidepressants.

RIAs are preferred for postmortem samples due to their resistance to matrix effects. Most other techniques are difficult to apply to these specimens.

Postmortem samples are homogenized in a deproteinizing medium such as acetonitrile or a mixture of zinc sulfate/sulfosalicylic acid/methanol. As a result of their sensitivity and low matrix effect, RIAs can detect low levels of lysergic acid diethylamide (LSD) in urine, ricin in tissues, and tetrahydrocannabinol (THC) in hair. Although RIAs have many analytical advantages and  $^{125}\text{I}$ , instead of  $^{131}\text{I}$ , has been used to label drugs in most current RIA methods because of its longer half-life, there are problems in disposing of radioactive waste and using an isotope with a short shelf-life (~60 days). These shortcomings have reduced the demand for RIA and manufacturers no longer make kits for common drugs.

EMIT<sup>®</sup> is a homogeneous assay that uses an enzyme (glucose-6-phosphate dehydrogenase) labeled drug to compete with unlabeled drug for a specific antibody. If the labeled drug is free from the antibody, the enzyme oxidizes glucose-6-phosphate and reduces  $\text{NAD}^+$  to NADH, which is measured at 340 nm with a spectrophotometer. Automated analyzers are available for these immunoassays, and hundreds of samples can be processed in an hour. While the EMIT<sup>®</sup> assay was developed for drugs in urine, it has also been applied to aqueous extracts from other biological samples (e.g., meconium). If a clear and nearly neutral solution can be obtained from a sample, then the sample can be assayed by EMIT<sup>®</sup>.

FPIA methods use a fluorescein-labeled drug to compete with the unlabeled drug for an antibody. If the fluorescein-labeled drug combines with the antibody, the emitted light remains polarized when the incoming light is polarized. As the concentration of drug in the sample increases, free fluorescein-labeled drug molecules also increase in number. Since the unbound fluorescein-labeled drug molecule rotates freely, the polarized light emitted is reduced. Automated analyzers, such as TDx<sup>®</sup>, ADx<sup>®</sup>, and Axysm<sup>®</sup> (Abbott Laboratories), are used to measure these reactions. Drugs are more accurately measured by FPIA than EMIT<sup>®</sup> because sample matrices have less effect on changes in fluorescein polarization.

CEDIA<sup>®</sup> is a relatively new technique that uses two genetically engineered fragments of *Escherichia coli*  $\beta$ -galactosidase as an enzyme label. The activity of the enzyme requires assembly of the two fragments, termed enzyme donor and enzyme acceptor fragments. The enzyme donor fragment is bound to a drug. The enzyme donor fragment-labeled drug competes with the drug present in urine samples for a specific antibody. When the enzyme donor fragment-labeled drug combines with the antibody, the fragment does not associate with the enzyme acceptor fragment and the enzyme activity does not

develop. When the enzyme donor fragment-labeled drug associates with the enzyme acceptor fragment, it becomes active and hydrolyzes chlorophenol red- $\beta$ -galactoside to chlorophenol red and galactose. Production of chlorophenol red is measured at 570 nm with a spectrophotometer. The concentration of the drug of interest is directly proportional to the change in absorbance and automated analyzers are commercially available.

KIMS<sup>®</sup> assay (Abuscreen Online by Roche Diagnostic Systems) uses microparticles labeled with several drug molecules. The drugs on the microparticles compete with the drug in urine for a specific antibody. Reaction of the drug molecules on the microparticle with several antibody molecules facilitates the formation of a large aggregate that increases absorbance. Thus, the concentration of the drug is inversely related to the change in absorbance. Since microparticle drug conjugates are more stable than enzyme drug conjugates, these kits have a long shelf-life.

ELISA is a sensitive and specific method that has been used for many years to detect body components and pathogenic microorganisms. However, its application to drug testing is relatively new. Since ELISA is a heterogeneous assay, it is not as sensitive to matrix effects. Thus, this technique is easily applied to postmortem fluid samples. A commercially available kit (MTA-8<sup>®</sup>, Venture Labs) can simultaneously test for eight drugs of abuse on one microtiter plate. MICROPLATE<sup>®</sup> Forensic EIA kits (OraSure Technologies) are also marketed.

Many immunoassay kits that do not require special instrumentation are commercially available. They do not require a formal laboratory and are used for on-site testing, such as driving-under-the-influence cases, workplace drug testing, and emergency room settings. These kits are also used in toxicology laboratories to test a relatively small number of samples at low cost. On-site drug testing devices use competitive immunoassay and the results are visualized as red bands of immunoreacted colloidal gold-labeled antibodies or drugs. The kits available for forensic on-site testing of urine are summarized in Table 3. Triage<sup>®</sup> DOA has been successfully applied to postmortem blood samples if the latter are properly pre-treated. For testing drugs-of-abuse in saliva, Cozart's RapiScan<sup>®</sup> (Cozart Biosciences) is the only device currently available.

Detecting agricultural chemicals in biological samples is important in forensic toxicology. A forensic toxicologist can use enzyme immunoassay kits (Rapid Assay<sup>®</sup>, Ohmicron Environmental Diagnostics) that were originally developed to monitor environmental chemicals, such as organophosphates, carbamates,

## Introduction

Few innovations have had as much impact on endocrinology, diagnostic, and clinical laboratory medicine as radioimmunoassay (RIA). It was the first technique to use radioisotopic technology to study the primary reaction of antigen with antibody. The

era of RIA can be said to have begun in 1959. Its development is attributed to the collaborative research developed by Rosalyn Yalow and Solomon Berson. By combining techniques from radioisotopic tracing and immunology they were able to investigate the metabolism of insulin labeled with radioactive iodine in diabetic adults. Over a considerable period RIA has proved to be a very sensitive and relatively simple means for measuring minute concentrations of biological and pharmacological substances in blood and other fluid samples. During the 1960s and 1970s, RIA emerged as an important tool in biological research. Knowledge in such diverse areas as endocrinology, cellular biology, and pharmacology was greatly expanded by the application of

this technique. Over the years the principle of RIA was adapted and nonradioactive labels, such as linked enzymes and fluorescent markers, have been used in place of radioisotopes. In this article, the basic principles of RIA are described, followed by a discussion of its potential and its limitations. Finally, several more recent applications of RIA are presented.

## Principle of Radioimmunoassay

The determination of a substance in biological fluid usually consists of at least two steps, reaction and detection. RIA depends upon the ability of an antibody to bind an antigen such as a hormone (or other molecule of interest) in a reversible fashion. Before discussing the principles of RIA, it is necessary to briefly define some immunological terms. An antigen

is a foreign substance that will induce the formation of immunoglobulins (antibodies) or sensitized cells that react specifically to the antigen. An antibody is an immunoglobulin that is formed in the body in response to a foreign substance (an antigen) and is specific to that substance. Antibodies to compounds too small to be antigenic can be produced by chemically linking the compound (a hapten) to an antigenic carrier such as bovine serum albumin and using this conjugate for immunization.

RIA employs isotopically labeled molecules and permits measurements of extremely small amounts of antigen, antibody, or antigen–antibody complexes. It can be used to measure any substance that will serve as an antigen or hapten. The concentration of labeled molecules is determined by measuring their radioactivity. This highly sensitive analytical method has many applications in hormone assays as well as for

**Figure 1** Simple illustration of the principle of a competitive radioimmunoassay where an antibody is immobilized onto a plate in order to detect the antigen in the test sample.

assays of other substances found at low levels in biological fluids. However, it is not an absolute technique and requires standards. The three basic requirements of RIA are a pure preparation of antigen (as standard), a radiolabeled preparation of antigen, and specific antibody to the antigen in question. RIAs belong to a group of assays known as radio-label assays. These can be divided into RIAs and immunoradiometric assays. RIAs are competitive assays for the detection of antigen where the radiolabel is on the antigen. The slightly less-sensitive immunoradiometric assay involves antibodies that are radiolabeled. In the late 1960s, researchers Miles and Hayes applied the term immunoradiometric to this assay format, although strictly speaking all RIAs are immunoradiometric.

The principle of any RIA involves competition between radiolabeled antigen and nonradiolabeled antigen for a fixed number of antibody binding sites. The antigen (labeled or unlabeled) can bind to its specific antibody to form an antigen-antibody complex. The presence of the radiolabeled antigen-antibody complex can be detected using a scintillation counter. In a standard solid-phase RIA, unlabeled antibodies with binding sites for the antigen of interest are coupled to a solid support such as plastic scintillation tubes or, as is more common nowadays, a 96-well microtiter plate.

Serial dilutions of the unknown sample of antigen (unlabeled) are added as in **Figure 1**. The concentration of the antigen in the unknown sample can be estimated by competitive inhibition with a standard sample of radiolabeled antigen molecules added in a known concentration. The antibody-bound antigen is separated from the unbound antigen. The separation of antibody-bound to labeled antigen from free labeled antigen enables the quantitation of antigen (either standard or unknown). A standard curve can be plotted that relates the concentration of antigen added with the labeled antigen in the bound fraction (where antigen has bound to antibody to form a complex) by setting up a series of tubes or microtiter wells containing progressively more standard antigen. At zero concentration of unlabeled antigen, a large proportion of labeled antigen will bind to antibody. However, the higher the concentration of unlabeled antigen, the less labeled antigen will bind to the fixed amount of antibody because of competition with unlabeled antigen (**Figure 2**).

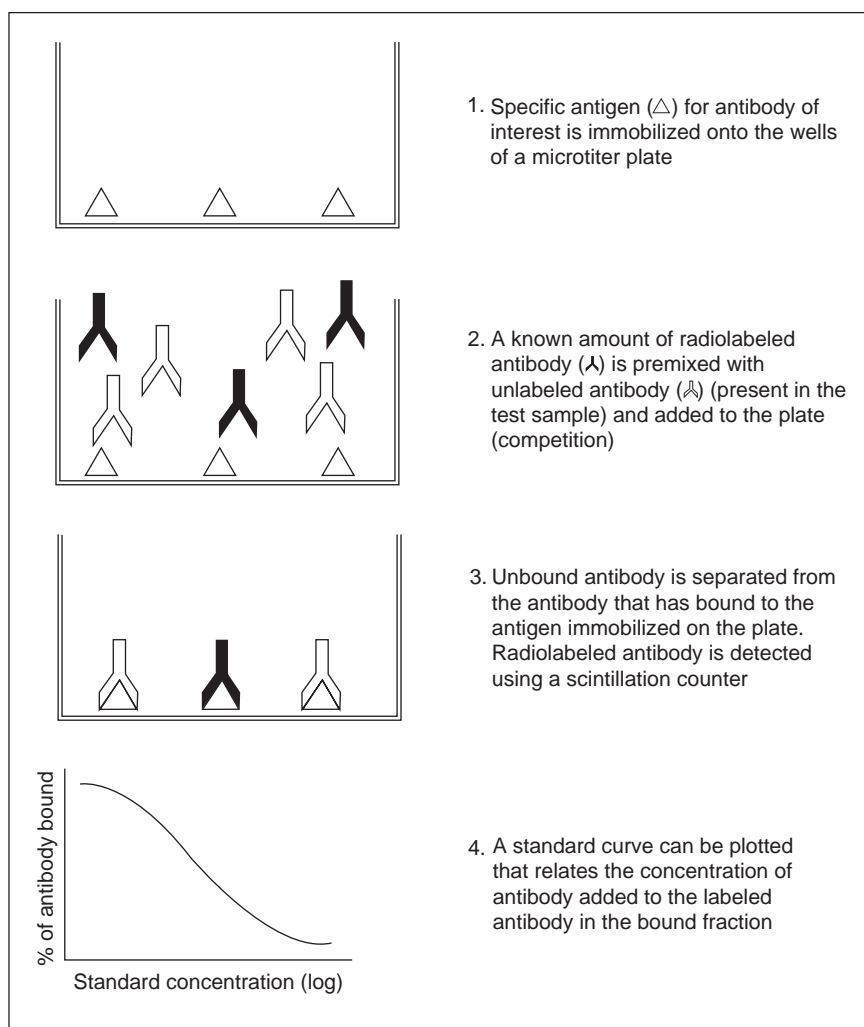

The standard curve has a linear scale of 'percentage of antigen bound' on the y-axis and a log scale of 'standard concentration' on the x-axis. The concentration of antigen in an unknown sample (e.g., hormone in a blood sample) can be calculated by

**Figure 2** Illustration of antigen-antibody interaction and how it is reflected in the resulting standard curve. (1) Both labeled and unlabeled antigens that have not bound to immobilized antibody are separated from the antigen that has bound to antibody. (2) Labeled antigen bound to immobilized antibody is detected using a scintillation counter and the values obtained are used to plot a standard curve.

observing the binding of radiolabeled antigen in that sample and reading it off the standard curve. **Figure 1** illustrates the principle of RIA.

So far the emphasis has been on the use of radiolabeled antigen rather than antibody. Use of radiolabeled antibody can be advantageous when detecting molecules such as IgE in patients suffering from allergies. Iodination of antibody rather than antigen may be favorable if the antigen is susceptible to damage during iodination, during storage, or if it lacks the necessary residues for iodination. In this situation, the antigen is fixed to the solid phase and is then reacted with unlabeled antibodies (e.g., from patients serum), in competition with labeled antibodies. Two modifications of the method for detecting antibodies have a major significance for allergy sufferers. These patients synthesize large amounts of IgE with binding sites for certain common, noninfectious environmental proteins, such as pollens. Patients need to be desensitized to the allergen, which first must be identified before treatment can begin. The first antibody detection method is known as radioallergosorbent test and involves the covalent linking of suspected allergens to cellulose discs, which are reacted with the patient's serum. Allergens that bind IgE from the patient's serum can be identified by indirect radiolabeling, using radiolabeled anti-human-IgE antibodies (**Figure 3**). The second method for detecting antibody is known as the radioimmunosorbent test. This assay measures the total concentration of IgE in patient's serum, regardless of its antigen specificity.

**Figure 3** Simple illustration of the principle of a competitive radiolabeled assay where an antigen is immobilized onto a plate in order to detect the antibody in the test sample.

## Radioimmunoassay Optimization

Several steps are involved in optimizing the development of an RIA and these are now discussed in sequence.

### Production of Radiolabeled Antigen or Antibody

There are four commonly favored isotopes for the labeling of antigen or antibody in RIA. These are  $^{14}\text{C}$ ,  $^3\text{H}$ ,  $^{125}\text{I}$ , and  $^{131}\text{I}$ , which vary greatly in their half-lives and their specific activities. A critical factor in the choice of a radioactive marker is the specific activity of the isotope. The importance of half-life in radioactive emission is evident when the relative specific activities of the different isotopes are calculated. A radioactive marker of low specific activity requires a relatively high concentration of this marker in

**Table 1** Details of specific activity and half-lives of four radioisotopes that are generally favored for the labeling of antigen or antibodies in RIA

Element	Radioisotope	Half-life ( $t_{1/2}$ )	Specific activity ( $\text{Ci mmol}^{-1}$ )
Carbon	$^{14}\text{C}$	5730 years	0.07
Hydrogen	$^3\text{H}$	12.3 years	33
Iodine	$^{125}\text{I}$	60 days	2560
Iodine	$^{131}\text{I}$	8.04 days	19250

order to obtain a practical level of radioactivity for use in the immunoassay. **Table 1** illustrates the half-lives and specific activities of the four most commonly used isotopes. With its combination of both long half-life and high specific activity,  $^{125}\text{I}$  is the most commonly used radioactive label for antigen binding in RIA. Compounds containing  $^{125}\text{I}$  tend to

be more stable than those with  $^{131}\text{I}$  because of the absence of beta radiation. The gamma radiation given off by  $^{125}\text{I}$  is less energetic than that of  $^{131}\text{I}$  and penetrates much less readily through glass and clothing.  $^{125}\text{I}$  is therefore much less of a radiation hazard than  $^{131}\text{I}$  for laboratory personnel.

For antigens that are unusually labile, it may be better to iodinate the antibody rather than the antigen. The antibody that contains numerous tyrosine residues can be substituted with several iodine molecules without adverse effects on antibody activity. The antibody is radiolabeled with  $^{125}\text{I}$ , usually after specific purification with antigen, to reduce or eliminate labeling of nonspecific gamma globulins.

There are a number of procedures for radiolabeling antigen or antibody. Radioiodine can be bound to tyrosine side chains via hydrogen substitution under alkaline conditions, or by conjugation as in the case of iodinated Bolton–Hunter reagent that reacts with lysine amino groups. This prevents the antibody being exposed to harsh chemical conditions, which may reduce the quality of the antigen or antibody.

### Production of Antibody

The performance of an RIA depends not only on the quality of the radioantigen, but also on the properties of the antibody. Traditionally, polyclonal antibodies were produced by immunization of an animal, such as a rabbit. The resultant antiserum contained many slightly different antibodies directed toward different antigenic sites on the antigen surface. Using hybridoma techniques developed in the 1970s it is possible to set up RIAs utilizing monoclonal antibodies from hybridoma cells secreting a single antibody type that bind specifically to one antigenic site on the antigen surface. Monoclonal antibodies are obtained by fusing mouse spleenocytes with myeloma cells to form hybridoma cells that secrete the antibody of interest.

### Optimization of Antiserum Dilution

The optimal working dilution of the antiserum is that which will bind 50–70% of the radioantigen in the absence of unlabeled antigen. A good antiserum with a high antibody titer will often be used in excess of a 1/10 000 dilution for RIA.

### Optimization of Antibody–Antigen Binding

In order to develop a sensitive RIA, the antibody must be capable of binding the antigen with high affinity. Antibody–antigen binding is reversible and utilizes noncovalent chemical bonding such as hydrogen bonding, electrostatic interactions, and van der Waal's forces. These types of chemical bonding

are sensitive to changes in pH and, therefore, it is important to determine the optimal pH that will give maximal antibody–antigen binding. Buffers can affect binding and so several buffer materials should be investigated at the optimal pH. Knowledge of the time taken for antibody–antigen binding to reach equilibrium is of importance when designing an RIA. This can be determined by assaying the proportional binding of a fixed amount of radioantigen to its antibody after various incubation times. Incubation times can vary from 1 to 72 h. Assays requiring greater than 4 h of incubation are carried out at 4°C to minimize possible degradation or denaturation of antibody and/or antigen.

### Separation of Antibody-Bound and Free Antigen

The final step in an RIA involves the measurement of bound or free antigen. Ideally, the separation procedure should be applicable to the simultaneous processing of a large number of immunoassay samples. In addition, separation should be achieved without undue dissociation of preformed antibody–antigen complexes or re-equilibration to form new complexes. Separation of antibody bound to antigen is a crucial step since incomplete separation would lead to a loss of assay precision and sensitivity. The choice of method for separating free and bound antigen depends on a number of factors, including the susceptibility of the antigen–antibody system to dissociation during separation, the solubility and absorption properties of the radioactive antigen, and the requirements of the assay in terms of speed and reproducibility.

If the antigen is a large polypeptide, a particularly useful method of separation is the so-called double-antibody technique. This method of separation utilizes a second antiserum that is raised to the gamma-globulin fraction of the animal species in which the primary antiserum was produced. Centrifugation will then leave the antibody-bound radiolabeled antigen in the supernatant. Either the supernatant or pellet containing radiolabeled antibody-bound antigen can be counted. The double-antibody method has the advantage of broad applicability, sensitivity, and reproducibility. If free antigen is of small molecular mass (i.e., a hapten), it is often possible to absorb it onto solid materials such as dextran-coated charcoal, silica gel, or hydroxyapatite. Salt or solvent precipitation or non-specific absorption methods permit more rapid measurements and, in general, utilize relatively inexpensive reagents. Specific immunoabsorbent systems may also lend themselves to rapid and sensitive measurements. Chromatoelectrophoresis or gel

**Table 2** Various separation methods and their application in RIA

<i>Separation method</i>	<i>Application</i>
Double-antibody method	Large polypeptide antigen Broad applicability, sensitivity, and reproducibility Can cross-react with human gamma globulins
Salt/solvent precipitation (e.g., NaCl/ethanol, chloroform)	Rapid, sensitive, and reproducible Inexpensive reagents Difficult to achieve complete separation
Nonspecific absorption method (e.g., dextran-coated charcoal, hydroxyapatite)	Small molecular mass antigen Rapid, sensitive and reproducible Careful separation needed to prevent erratic results
Specific immuno-absorbent system (e.g., sepharose matrix)	Rapid, simple, and sensitive Difficult to achieve reproducible levels of binding
Chromatoelectrophoresis	Detects incubation damage to radiolabeled antigen Laborious and expensive
Gel filtration	Requires careful monitoring of column/laborious Low sample capacity

filtration separation methods are more laborious and less desirable in general.

Another approach to separating the antibody-bound antigen is to immobilize the antibody. Many commercial RIA kits are now supplied where the antibody is attached to a particulate solid support such as Sephadex and can be pelleted by centrifugation. Another separation method that can be applied in RIA kits is magnetic separation. An example of this is an RIA kit for the detection of progesterone that uses  $^{125}\text{I}$  labeled progesterone and a progesterone-specific antibody bound to magnetic polymer particles. The progesterone bound to the antibody-magnetic polymer complex is separated from free progesterone by using a magnetic field. Table 2 refers to details regarding the various separation methods available.

## Measurement of Radioactivity

Scintillation counting devices exploit the property of certain chemical compounds to emit short light pulses after excitation by the passage of charged particles or by photons of high energy. Radioactivity is the property of an unstable isotope emitting energetic

particles and rays from its nucleus. The amount of radioactive material is measured by how many nuclei decay each second. This is called the activity and is measured in units of curies, abbreviated Ci. There are four basic types of radiation (alpha ( $\alpha$ ), beta ( $\beta$ ), gamma ( $\gamma$ ), and neutron (n)) emitted during decay. These types can be emitted alone or in combination with one another. Radiation ( $\gamma$ - or  $\beta$ -rays) emitting from radiolabels is detected by the combination of a scintillator and a photomultiplier tube, so that the antigen of interest can be quantitatively measured. Most radioactive isotopes such as  $^{75}\text{Se}$  emit  $\gamma$ -rays; however, there are some exceptions (such as  $^3\text{H}$ ,  $^{14}\text{C}$ ,  $^{32}\text{P}$ ,  $^{35}\text{S}$ , and  $^{45}\text{Ca}$ ) that are known as  $\beta$ -emitters. Different scintillation devices are used depending on the type of radiation emitted. Crystal scintillation counters are solid-state radiation detectors for radioactive isotopes that emit  $\gamma$ -rays. This device uses a scintillation crystal (phosphor) to detect radiation and produce light pulses. There are three classes of solid-state scintillation phosphors: organic crystals, inorganic crystals, and plastic phosphors.

The solid crystal scintillators (e.g., sodium iodide crystal) give off a flash of yellow light when they absorb  $\gamma$  radiation. A photomultiplier, which is optically coupled to the sodium iodide crystal, produces a pulse every time it 'sees' a scintillation. The pulse is then amplified and measured in order to determine whether it is of sufficient intensity and of a certain discrete energy level characteristic of the isotope chosen for measurement. The measurements from a crystal scintillation counter are in counts per minute.

Liquid scintillation counters are designed to detect isotopes that emit low levels of  $\beta$  particles, which are electrons that carry a single electrical charge. These devices are extremely sensitive and can detect radioactivity below the detection limits of traditional Geiger counters.  $\text{H}^3$  emits a very low energy  $\beta$  particle that can only travel about half a centimeter in air. Therefore, these low-energy  $\beta$  particles are measured using a liquid scintillation counter. The  $\text{H}^3$  sample can be suspended in a mixture that acts similarly to the sodium iodide crystal.  $\beta$  energy is absorbed into the mixture and produces flashes of blue light. This blue light is detected and measured by photomultiplier tubes in a similar manner to the crystal scintillator, and the pulse height represents the energy of the  $\beta$  particle.

Scintillation counting device advantages include their efficiency, high precision, and accurate counting rates. The latter two attributes are a consequence of the extremely short duration of the light flashes, from  $\sim 10^{-9}$  to  $10^{-6}$  s. The intensity of the light flash and the amplitude of the output voltage pulse are

proportional to the energy of the particle responsible for the flash. Consequently, scintillation counters can be used to determine the energy, as well as the number, of the exciting particles. Recently, the quantity of samples and the number of items to be measured for assays are rapidly increasing. Therefore, equipment for RIAs has been automated, for example, the well scintillation counter that utilizes crystal scintillators. Measurements are made by automatically inserting test tubes, which contain a mixture of antigens and antibodies including labels, into each hole in the scintillator. Each detector section including a scintillator is covered by lead shield to block extraneous radiation.

## Safety Aspects

The equipment and facilities normally available in a pathological laboratory or a hospital can be readily supplemented and used for RIA work. A license must be obtained and adequate training is required in order to permit the handling of radioactive material in any facility. If RIA kits are employed, there is generally no significant radiation exposure to the working personnel. However, precautions should be taken to safeguard against spread of contamination to the scintillation tubes and the scintillation device itself. This can be achieved to a large extent by good work practice. For example, any liquid waste arising from the RIA procedure should be disposed of in accordance with the relevant national and international safety regulations. The personnel engaged in the actual work should have adequate knowledge of the basic procedures of RIA and how to use the scintillation device. They should be aware of the necessary precautions taken when handling radioactive substances and all RIA facilities should provide their staff with access to an RIA safety-training course. The following list illustrates some important facility requirements when first establishing an RIA laboratory:

1. RIA scintillation device for measurements.
2. Benches/areas specifically designed or covered to ensure radioactive contamination cannot be absorbed.
3. Sink with smooth finish and elbow operated taps; foot operated waste bins.
4. Washable paint on all walls, doors, etc., and PVC/linoleum or other suitably covered floors.
5. Separate rooms for source storage and radioactive waste, waste receptacles for collection and storage of liquid and solid radioactive waste.
6. A portable contamination monitor.
7. Items for protection of users, where relevant, e.g., shields.

8. Clear and well designed standard operating procedures.

The documentation of the radiation dose received by personnel working with radioactive material is critical to minimizing such exposures. The most suitable approach to monitoring occupational radiation exposures in individuals is through the use of a personal dosimeter. The appropriate use of the radiation monitoring dosimeters is essential to minimize radiation exposure and they are minimally intrusive to the worker. The dosimeters are usually configured as lapel clips or finger rings. Wristband badges are utilized in circumstances where a ring badge is not suitable.

## Advantages and Limitations

RIAs offer many advantages in terms of specificity, sensitivity, and convenience, but they also have inherent limitations and disadvantages. Some of the limitations are unique or largely restricted to immunoassays. Other limitations represent more general problems in interpretation that arise when quantitative measurements in tissue, blood, or urine are used as an index of what the physiologic or pharmacologic response might be in an organism as a whole.

A major advantage of RIA is that it combines specificity of immunoassays with the sensitivity of radiochemical methods. Concentrations in the picomolar region can be measured accurately. Regardless of the exact RIA procedure used, the great advantage of all RIAs is their sensitivity. Commercially available kits may detect as little as 1 ng or pg of antigen. This is obviously of great significance in monitoring or determining blood levels of certain hormones or therapeutic agents that seldom exceed a few micrograms per milliliter. The purpose of RIA is similar to enzyme-linked immunosorbent assay (ELISA), i.e., to quantitate antigen or antibody. However, when a higher level of sensitivity is needed, plate-bound radioactivity is used for detection rather than color. RIAs used to be carried out in tubes rather than in microtiter plates (as is the case for ELISA) to facilitate radioactive measurements in a scintillation counter. Now, however, with the availability of suitably designed microtiter plates and scintillation counters, solid-phase RIAs using a microtiter format are possible.

RIA also has some notable disadvantages, which include the need for expensive reagents and equipment and the requirements for licensing and containment. Criticism of the use of radiolabels has focused on their relatively short half-life, and

**Table 3** Potential of RIA and its limitations

<i>Advantages</i>	<i>Disadvantages</i>
High sensitivity, good specificity	Expensive instrumentation
Good reproducibility (as far back as Yalow and Berson's work in 1950s)	Special training and license required Disposal of radioactive waste
Availability of RIA kits to a wide range of antigens	Reagents subject to decay (e.g., short half-life of some isotopes)
Well-established formats and labeling procedures	Laboratory safety issues

relatively long counting times required in order to achieve good statistical accuracy, their limited shelf-life, the expense of disposal and concern over general laboratory safety. **Table 3** illustrates both the advantages and disadvantages associated with the use of RIAs.

## Applications

Since the early 1960s, RIAs and other competitive binding assays have been developed to a remarkable array of biochemically or pharmacologically important substances and in many instances have virtually replaced other methods of measurement. RIA is commonly used to measure the low concentrations of peptide and protein hormones that occur in blood. It is widely used both in routine clinical chemistry laboratories and in research laboratories. In this section, important applications developed in the past will be surveyed and recent developments of RIA in areas such as endocrinology and pharmacology shall be reviewed in detail.

### Endocrinology

Due to the relatively long historical association of RIA with endocrinology there has been a vast amount of research carried out since Yalow and Berson performed their work on insulin. Among the early applications (during the 1960s) in this field were immunoassays for growth hormone, corticosteroids, bradykinin, angiotensin II, prolactin, and vasopressin. In subsequent years, RIAs were developed for other major hormones, including estrogens, progesterones, androgens, calcitonin, prostaglandins, and human chorionic gonadotrophin. Some of the important general applications of immunoassays to endocrinologic studies have been as follows:

1. Clinical laboratory measurements for differential diagnosis of endocrine disorders.
2. Determination of hormonal content of different tissues.
3. Studies on the effect of anti-hormone antibodies on hormone activity and metabolism.
4. Recognition and investigation of endocrine-secreting tumors.

'Ready-to-use' RIA kits have been utilized in many studies due to their ease of application and commercial availability for detection of a vast range of hormones. Evaluation of thyroid hormones using RIA kits has helped in the diagnosis of hypothyroidism and hyperthyroidism. Other kits detect human chorionic gonadotrophin for fetal monitoring and angiotensin-1 for differential diagnosis of hypertension. Another commercially available kit is utilized for the quantitative measurement of enzymatically and chemically derivatized noradrenalin and adrenalin in plasma and urine. Some RIA kits have been modified to suit the researcher's needs. Researchers at a behavioral endocrinology laboratory have recently developed a simple, reliable, and highly sensitive assay by modifying commercially available RIA kits for the measurement of estradiol in saliva and blood spot specimens. In 2002, a conventional  $^{125}\text{I}$  RIA was adapted to a microtiter plate format. This is of considerable importance when dealing with a large batch of samples. The  $12 \times 75$  mm scintillation tubes are still commonly used for routine experiments. However, if large batch samples are to be tested this method can be laborious. Commercial microtiter plates have been available for some time but they can be expensive. A novel microtiter format was developed in order to cut the cost and the time (reduced from 4 to 1.5 h per 384 assay tubes) it takes to run these assays. This mini-RIA contains a simple draining device for batch decantation of free antigen from 96-well 1.2-ml mini-tubes. This assay also showed increased sensitivity when compared to conventional RIAs. Since the format of this assay is flexible, most conventional assays can utilize this method for batch samples.

RIAs are used extensively in hormone detection in both serum samples and saliva samples. An example of this involves the development of a specific RIA to detect estrone sulfate in male plasma samples. Estrone sulfate is quantitatively a major circulating plasma estrogen in both female and male humans. It has been widely studied, especially its metabolism, in breast cancer tissues.

Concern has been raised about the adequacy of RIAs for the measurement of steroid sex hormones in population studies. Sex hormones play an important role in regulating growth, maturation, and reproduction and are believed to be of etiologic

importance in several chronic diseases including prostate and breast cancers, osteoporosis, and cardiovascular disease. A recent study was completed by Dorgan and co-workers in order to determine if RIA is an adequate assay system for measuring sex hormones. The investigation involved the comparison of steroid sex hormone measurements in serum by RIA with mass spectrometry. Samples were taken from both male and female pools. Estradiol, estrone, androstenedione, testosterone, and dehydroepiandrosterone sulfate were measured in female pools; testosterone, dihydrotestosterone, androstenedione, and dehydroepiandrosterone sulfate were measured in male pools. The findings of this study indicate that although absolute concentrations may differ for some hormones, RIA and mass spectrometry can yield similar estimates of steroid sex hormone concentrations in serum.

A study by De Niu and co-workers reported an RIA to detect human stanniocalcin in serum and tissue samples. Stanniocalcin is a polypeptide hormone first discovered in fish but only recently identified in humans and other mammals. Before this assay was developed there was no information on circulating levels of stanniocalcin in mammals or the regulation of its secretion. The RIA for detecting stanniocalcin was developed to help explore the possibility that stanniocalcin may have a short half-life in mammals. From the pharmacokinetic data obtained from this research it was determined that mammalian stanniocalcin does not normally circulate in the blood and functions instead as a local mediator of cell function. Another RIA was developed recently to detect vasoactive intestinal polypeptide (VIP). VIP belongs to the family of related peptides containing secretin, glucagons, and growth hormone-releasing hormone. The assay has helped to gather data regarding the comparative distribution of VIP in the central nervous system of various species. A separate study has used both RIA and real-time quantitative polymerase chain reaction to understand the regulation of neurotrophic peptide expression in sympathetic neurons.

RIA has found uses in other areas besides the medical and healthcare sector. Assays have been developed for the agricultural sector. For example, a blood spot direct RIA has become a useful tool for early pregnancy diagnosis in swine with an overall assay accuracy of 96.8%. The assay works by detecting progesterone in blood dried onto filter paper. This method is versatile as it can be used for monitoring progesterone levels during the estrous cycle so that the optimal time for artificial insemination can be estimated. RIAs are also helping to expand knowledge of insect endocrinology. Adipokinetic hormone concentrations in the hemolymph of *Schistocerca gregaria*

(locust) have been measured by an RIA developed in the University of Birmingham.

### Pharmacology

Among the early contributions in this field were immunoassays for digitoxin and morphine. RIAs have subsequently been applied to the measurements of prostaglandins, barbiturates, gentamycin, amphetamines, and vitamins A and D. Important general applications of immunoassays to pharmacology include the following:

1. Detection of drug abuse using rapid and convenient screening procedures.
2. Diagnosis of suspected drug poisoning.
3. Monitoring routine drug therapy with drugs subject to uncertain absorption or metabolism.
4. Studies on drug absorption, distribution, metabolism, and excretion.

Some of the recent RIA developments are quite diverse with regard to pharmacology and include vitamin D detection, illicit drug detection in hair samples, and antibiotic detection in livestock.

Analytical and clinical validation of an RIA for the measurement of 1,25-dihydroxyvitamin D was performed by Clive and co-workers. Vitamin D is a critical regulator of calcium and phosphorus homeostasis. This assay was specific for both 1,25-dihydroxyvitamin D<sub>2</sub> and D<sub>3</sub>. The data collected during this study demonstrated that the RIA validated was a robust, accurate, and precise tool for the assessment of vitamin D.

An area of pharmacology that holds immense interest and importance is illicit drug detection. A commercial RIA kit has been used in an Italian laboratory to detect morphine, cocaine, and ecstasy constituents in extracts of hair samples. This diagnostic strategy has been applied to determine whether former users of illicit drugs are fit enough to obtain a driving license.

A commercially available RIA developed as a screen for tetracycline antibiotics in serum, urine, milk, and tissue of livestock has been adapted by Meyer and co-workers to analyze water samples. The interest in pharmaceutical compounds in the environment is relatively new. Immunoassays for pharmaceutical compounds are commonly used in biological media where the concentrations are quite high. Therefore, in this RIA the lower limit of antibiotic detection had to be modified to enable quantification of antibiotic levels as low as one part per billion in water samples.

Other areas where RIA has found some application include the diagnosis of infectious diseases, oncology, cardiology, and hematology.

It seems that ELISA will replace RIA as it has many advantages over RIA. Despite the continual prediction of doom for the use of isotopic labels for analysis they continue to be widely utilized. This stems in part from well-established methods of preparation, optimization, a history of highly reproducible performance, and the wide availability of scintillation-counting equipment. In certain applications, such as imaging, there are still few if any real alternatives to the use of radiolabels.

## Enzyme Immunoassays

**Y Seo**, University of Miyazaki, Miyazaki, Japan

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

Immunoassays are used for the detection of a wide variety of biological and serological substances. They are generally classified into two groups, labeled and unlabeled immunoassays. Labeled immunoassays include antigen or antibody conjugated with radioisotopes, fluorescent materials, metals, enzymes, and other reagents. In enzyme immunoassays (EIAs), an enzyme conjugate can be used to produce a very sensitive colored, fluorescent, or luminescent output.

EIAs have been developed over the last 30 years, and in the last 10 years their use has become

widespread throughout the sciences, including medicine, pharmacology, toxicology, biology, ecology, and food chemistry. This popularity is due to the fact that they can be more sensitive, specific, and simple to use than other types of analytical techniques. The sensitivity of the assay can be manipulated at a variety of steps, including the specifics of the assay procedure, the selection of the enzyme for conjugation, the reaction conditions for the enzyme, the conjugation protocol, and the antibody preparation.

Rapid EIAs have been developed for the diagnosis of viral infections as well as for the identification of valuable markers for carcinomas. Using commercially available kits, these EIAs can be utilized even in laboratories with very limited facilities. In this article, we discuss the advances and improvements of EIAs in the last 10 years and supplement the basic

information presented in the section Enzyme Immunoassays in the first edition of the *Encyclopedia of Analytical Science*.

## Sensitivity of EIAs

The sensitivity of EIAs is mainly influenced by the assay procedures. Improvement of these variables has led to the development of extremely sensitive EIAs for antigens, antibodies, and haptens. For example, in some cases, the antigen detection limit is at the one zeptomol ( $1 \times 10^{-21}$  mol) per assay ( $33 \text{ zmol ml}^{-1}$ ) level.

## Basic Procedure

EIAs are classified as either homogeneous or heterogeneous. In homogeneous EIAs, the enzyme activity is altered by the interaction of labeled antigen and antibody. Because the degree of signal changes in proportion to the concentration or amount of antigen, separation of the bound and free (B/F) antigen is not required. Although this technique is rapid and can be applied in some limited cases, it is not generally useful for the development of highly sensitive EIAs. In contrast to the homogeneous assays, heterogeneous EIAs require B/F separation prior to the measurement of enzyme activity. Such a separation of B/F antigen is also used in radioimmunoassays. In general, the heterogeneous method is much more sensitive than the homogeneous method because interference from free ligand is eliminated.

In addition to the heterogeneous and homogeneous assays, EIAs can be classified as competitive or noncompetitive. In competitive EIAs, labeled antigen competes with unlabeled antigen in the test sample for a limited amount of bound antibody. In this case, the signal is due to the amount of bound, labeled antigen-antibody complex, and the decrease in enzyme activity corresponds with the concentration of unlabeled antigen in the test sample. In the noncompetitive method, the signal is due to the direct binding of the labeled antibody complex to the antigen, so that it essentially corresponds directly to the amount of antigen in the test sample.

These four methods have been combined to develop a number of EIAs for quantifying antigens, antibodies, and haptens. For example, the enzyme multiplied immunoassay technique (EMIT<sup>®</sup>) is a commercially available homogeneous and competitive EIA for the determination of a variety of drugs. In addition, double antibody methods that utilize a heterogeneous and competitive EIA system are available. In this case, enzyme-labeled antigen and sample antigen are mixed

with an unlabeled primary antibody in solution, and once this first immunoreaction is over, a secondary antibody, typically anti- $\gamma$ -globulin, is added to bind and precipitate the primary antibody-antigen complex. Finally, B/F separation is performed and enzyme activity is measured. However, this assay procedure typically lacks sensitivity because it is a competitive assay wherein small amounts of antigen produce do not significantly decrease the signal.

## Enzyme-Linked Immunosorbent Assay

A significant improvement of these solution-based EIA methods is to utilize antibodies or antigens coupled to a solid support. These are called enzyme-linked immunosorbent assays (ELISAs), and are extremely sensitive. This system requires rapid binding of the antibody or antigen to the solid phase and stability of this complex through multiple steps of washing. The solid phase is typically a latex emulsion, plastic or glass beads, polystyrene balls, or microtiter plate wells. These ELISA techniques are principally heterogeneous EIAs, and there are both competitive and noncompetitive versions.

An example of a competitive ELISA is shown in **Figure 1**. This simple method can be used to measure a wide variety of antigens, antibodies, and haptens. The first step in this assay is the preparation of an antibody-coated solid phase. In many laboratories, this is accomplished by physical adsorption, for example, to the wells of a polystyrene microtiter plate. Next, a known amount of enzyme-labeled antigen and an unlabeled antigen-containing sample is added to the immobilized antibody. Competition of the labeled and unlabeled antigen for the antibody occurs on the solid phase. After this binding step, the unbound antigen is removed by washing. Finally, the bound enzyme-labeled antigen is assayed by addition of a substrate solution (**Figure 1**). In this system,

**Figure 1** A typical competitive ELISA for the determination of antigen. The antigen in the test sample competes with enzyme-labeled antigen for binding to the antibody.

because there is competition for the labeled antigen, the higher the level of antigen in the test sample, the lower the signal. This protocol can also be applied to an antigen capture immunoassay, which is used for the determination of the antibody concentration in a test sample. In this case, the antigen is coupled to the solid phase, and the competition is between a known amount of labeled antibody and the unlabeled antibody in the test sample. In most cases, these competitive ELISAs can achieve femtomole ( $1 \times 10^{-15}$  mol) per assay or higher sensitivities, which is equivalent to the sensitivity of radioimmunoassay. One potential problem with these assays is that the enzyme-conjugated antigen can be too large and obstruct the reaction between the labeled antigen and the antibody-coated solid phase.

### Sandwich ELISA

Two-site enzyme immunoassay or the so-called sandwich enzyme immunoassay (sandwich ELISA) is widely used in many laboratories as a more specific and sensitive assay than other EIAs. This method is a heterogeneous and noncompetitive type of EIA. The principle of this system is shown in Figure 2. This system is more versatile than other EIAs, especially for detection of protein antigens, and it can achieve attomole ( $1 \times 10^{-18}$  mol) per assay sensitivity. Sandwich ELISAs utilize both an antibody-coated solid phase and an enzyme-labeled antibody. In the first step, the antigen is bound to the antibody-coated solid phase, and the unbound antigen is removed by washing. Next, the enzyme-labeled antibody is added, and, after the incubation and immunoreaction are complete, the unbound enzyme-labeled antibody is removed by washing. Finally, the amount of bound enzyme-conjugated antibody is determined by assay

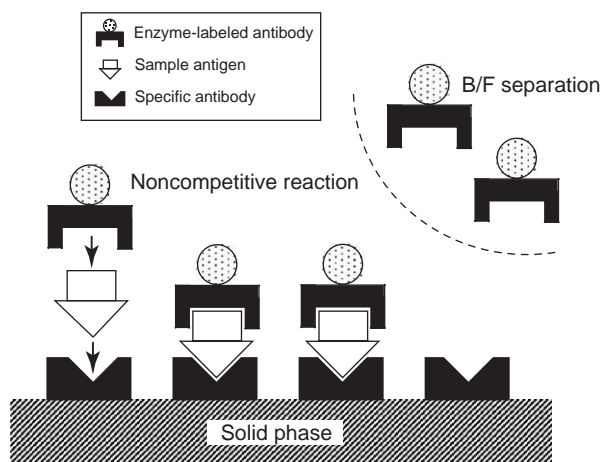

of the enzyme activity. In this case, the enzyme activity corresponds directly to the amount of antigen. Due to the washing, there is little nonspecifically bound labeled antibody. Therefore, background signals are very low, and the system is highly sensitive.

There are variety of sandwich ELISA systems. For example, in indirect sandwich ELISAs, the assay uses an unlabeled primary antibody for the sandwich step in conjunction with an enzyme-labeled anti-immunoglobulin secondary antibody. This system can also employ a biotinylated sandwich antibody and enzyme-labeled streptavidin for detection. The indirect sandwich ELISA can be used not only for detection of antigens but also for measurement of antibody concentration, a system more specifically referred to as an indirect antibody capture immunoassay. In this case, an antigen-coated solid phase is prepared and then incubated with a serum or plasma test sample. Next, a secondary enzyme-labeled anti-immunoglobulin antibody or enzyme-labeled antigen is added, unbound reagents are removed by washing, and enzyme activity is assayed.

Although these ELISA systems are usually carried out in microtiter plates and with colorimetric enzyme reactions, the assays may be even more sensitive using small polystyrene balls (of 3 mm diameter) as the solid phase along with a fluorometric enzyme assay. In fact, such fluorometric assay systems can achieve 0.3 attomol per assay ( $10 \text{ mol ml}^{-1}$ ) sensitivity. There are, however, some limitations to the sandwich ELISA. For example, the sandwich system requires two immunoreactions, first to bind antigen to immobilized antibody, and, second, to bind the sandwich antibody. Therefore, the antigen must have more than one antigenic epitope. As a result, it may not be possible to assay small haptens with this technique. Also, a single monoclonal antibody cannot be used both for coupling to the solid phase and as the sandwich antibody. However, a polyclonal antibody could be used both as the coupling and sandwich antibodies because it contains a heterogeneous mixture of antibodies against multiple antigen epitopes.

### Immune Complex Transfer Immunoassay

Currently, one of the most sensitive EIA methods is the immune complex transfer immunoassay, which is a heterogeneous and noncompetitive EIA. This system can measure zeptomole per assay levels of protein antigens and antibodies as well as attomole per assay levels of several haptens. In this method, the primary immune reaction occurs on a solid support, after which the immune complexes are specifically

**Figure 2** A 'sandwich' type enzyme immunoassay for the detection of an antigen.

eluted. Next, the eluted immune complexes are trapped on a second solid phase, enzyme-labeled reagents are added, and, finally, enzyme activity is assayed. This technique is extremely sensitive because it greatly reduces nonspecific binding of labeled reagents.

The immune complex transfer assay has allowed the development of very sensitive EIAs for the detection of antibodies. In one example, the assay utilizes a 2,4-dinitrophenyl (DNP)–biotin-conjugated antigen. This is incubated with the sample antibody to be measured, and, after the immune reaction, the immune complexes are trapped onto a primary solid phase coupled with anti-DNP antibody. After washing away unbound materials, immune complexes are eluted with DNP–lysine and transferred to a secondary streptavidin-coated solid phase. Next, an enzyme-labeled anti-immunoglobulin antibody is added, and, after washing, enzyme activity is assayed. In this case, the enzyme activity correlates with the amount of antibody in the sample. The sensitivity depends on the amount of nonspecific binding of the enzyme-labeled antibody on the second solid phase. Thus, several modified assay systems have been developed to reduce background.

## Enzyme and Enzyme Labeling

Generation of enzyme-conjugated antigens or antibodies is the most important aspect of EIAs. The enzyme selected for labeling must correspond to the

needs of the individual EIAs. In addition, the methods used for enzyme conjugation must be selected to maintain antigen-binding activity and to prevent nonspecific binding.

## Enzyme

Selection of the enzyme for conjugation is a principal factor in the development of EIAs. The enzyme selected must be of high purity, there must be a good assay for the enzyme, and there must be instrumentation for the detection of the products of the enzyme reaction. Also, the enzyme must be stable during storage, enzyme conjugation must be possible under neutral conditions, and conjugation must not damage the activity of the enzyme. There are only a few enzymes that satisfy these requirements. Therefore, emphasis has been placed on the development of highly sensitive assays and detection methods for these few enzymes.

Detection methods for the enzyme reactions include colorimetric, fluorometric, chemiluminometric, and bioluminometric assays, as well as electrochemical methods, and their detection ranges vary. The principal enzymes used for labeling, assay methods available, and levels of sensitivity are summarized in Table 1. Amongst these, horseradish peroxidase,  $\beta$ -D-galactosidase from *Escherichia coli* (*E. coli*), and alkaline phosphatase from calf intestine or *E. coli* are currently the most widely used for conjugating antigens or antibodies.

**Table 1** Assays and approximate detection ranges of enzymes used in EIAs

Enzyme	Assay	Detection range (mol/assay)			
		$10^{-12}$	$10^{-15}$	$10^{-18}$	$10^{-21}$

## Enzyme Labeling

A variety of methods and reagents for coupling an enzyme to an antigen or antibody have been developed. Of these, glutaraldehyde is the most commonly used because it easily reacts with amino groups under mild conditions, and stable enzyme conjugation is accomplished within a few hours. While this one-step method is simple and applicable to almost all proteins, the labeling is nonselective, and heteropolymers are frequently formed, which can interfere with antigen-antibody binding. Two-step coupling methods generally avoid these problems, although they also may use glutaraldehyde as the coupling agent. In this process, one of the components is labeled with the coupling reagent, after which the excess reagent is removed by dialysis or gel filtration. Finally, the conjugated component is reacted with the second component to form the final product. Peroxidase- or alkaline phosphatase-labeled antibody is often prepared using this method, but the production of heteropolymeric products is not avoided, and the recovery of conjugated antibody is very low.

In addition to glutaraldehyde, periodate can be used to prepare antibody or antigen conjugates. Periodate reacts with glycoprotein carbohydrates to generate reactive aldehyde groups. These aldehyde groups can react with amino groups to form a stable covalent bond. This method is very effective for labeling antibodies with peroxidase because it contains ~18% by weight of carbohydrates, and the reaction does not interfere with enzyme activity.

A number of maleimide derivatives are used for coupling reagents to introduce maleimide groups into enzymes and antibodies. The maleimide groups in these reagents react efficiently with thiols to form stable covalent bonds. Free thiol groups can be produced in the hinge portion of antibodies by mild reduction, and some enzymes, such as  $\beta$ -D-galactosidase from *E. coli*, naturally contain free thiols. Pyridyldisulfide groups can also be used to

conjugate thiols, but the efficiency of coupling is lower than for maleimides. Although a variety of coupling reagents are synthesized and available, they require satisfying some important factors, such as solubility, stability, reactivity, and purity. Maleimide, thiol, and pyridyldisulfide derivatives are frequently less soluble in the buffer, but almost all of these may be soluble in *N,N*-dimethylformamide. Maleimide groups of some maleimide derivatives are stable at acidic pH value; however, their reactivities are obstructed in the presence of  $\text{NaN}_3$  as an antiseptic. The reactions between maleimide and thiol groups are usually completed within 5–10 h at 4°C or 1 h at 30°C subjected to the weakly acidic condition. The purity of coupling reagents is also essential to obtain sufficiently good results.

There are two categories of methods for conjugating antibodies with enzymes: hinge and non-hinge methods. Hinge methods label the antibody in the hinge region, while nonhinge methods label the antibody at other sites. The nonhinge method includes the use of glutaraldehyde or periodate because these reagents can label throughout the antibody. IgG molecules are liable to fragmentation by proteolytic attack by enzymes. Fab and  $\text{F(ab')}_2$  fragments containing the entire L chain and disulfide linked portion of the H chain can be produced by digestion with papain and pepsin, respectively. The  $\text{F(ab')}_2$  fragment is divalent and the Fab fragment is univalent, and Fab fragment binds to the antigen through non-cross linkage and precipitation. Hinge methods frequently use mild reduction of  $\text{F(ab')}_2$  to produce free thiols in the hinge region of  $\text{Fab'}$ , followed by the use of maleimide-based coupling reagents. **Figure 3** depicts enzyme conjugation using a maleimide-hinge method. Enzyme-labeled antibodies produced using the maleimide-hinge method, such as  $\text{Fab'}$ -peroxidase conjugates, have many advantages, including the absence of heteropolymers and full maintenance of enzyme and antigen-binding activity. In addition, in the case of  $\text{Fab'}$ -peroxidase conjugates, nonspecific binding is low because they lack the hydrophobic Fc

**Figure 3** Conjugation of  $\text{Fab'}$  with enzyme using the maleimide-hinge method.

portion of IgG, which frequently causes nonspecific binding.

## Antibody

The preparation of antibody is another important factor for the development of EIAs. High affinity and specificity antibodies are needed for the development of sensitive and specific EIAs. Fab'-enzyme conjugates prepared using maleimide-hinge methods may become indispensable in this regard. Furthermore, affinity purification of antibody and/or enzyme-labeled antibody as well as utilization of monoclonal antibodies may also be needed for the development of specific and sensitive EIAs. Although several bimolecular approaches that are producing recombinant antibody possessing enzyme activity have been attempted, sufficiently good results have not yet been acquired and practical usages have not been accomplished.

### Preparation of Fab'

Fab' is often used along with the maleimide-hinge method of enzyme conjugation. F(ab')<sub>2</sub> can be prepared from rabbit, goat, sheep, guinea pig, rat, mouse, and capybara IgG by digestion with pepsin. The IgGs in this case can be purified by precipitation with saturated sodium sulfate, followed by DEAE ion-exchange chromatography. Antibody can also be purified using proteins A or G. Fab' is generated from F(ab')<sub>2</sub> by reduction under mild conditions, often with 2-mercaptoethylamine because it does not damage antigen-antibody binding. This also generates free thiol groups in the hinge region of Fab', which can be conjugated with maleimide (Figure 3). Because  $\beta$ -D-galactosidase from *E. coli* naturally has many thiol groups, maleimides can easily be conjugated to the reduced Fab'.

### Affinity Purification of Antibodies

ELISA systems are typically 10- to 100-fold more sensitive when they utilize affinity-purified antibodies instead of unpurified antibodies. Coupling of affinity-purified antibodies to the solid phase can result in an increase in background because minute amounts of antigen-antibody complexes can be eluted with the affinity-purified antibody and because antibodies can be damaged during elution procedures. To avoid these problems, the enzyme-conjugated antibody should be affinity purified, or an affinity-purified antibody should be used for enzyme labeling.

Antibodies are affinity purified by binding them to immobilized antigen. The most common solid support for immobilizing antigen is cyanogen bromide-activated Sepharose. Almost all antigens containing amino

groups can be conjugated in this way to this resin. Ligands containing carboxyl, sulfhydryl, or aldehyde groups can also be attached to support materials.

### Monoclonal Antibodies

A large number of monoclonal antibodies with high specificity and affinity are commercially available for a variety of antigens. Although many EIAs using monoclonal antibodies have been developed, the antigen-binding activities are frequently reduced due to covalent attachment and/or the solid phase. For sandwich ELISAs, two distinct monoclonal antibodies that react with different sites on the same antigen are necessary. Alternatively, a monoclonal antibody can be used in conjunction with a polyclonal antibody to the same antigen.

### Preparation of Immobilized Antibodies

Antibodies are commonly immobilized to solid supports by either physical adsorption or covalent linkage. Although glutaraldehyde can be used to couple antibody or antigen to a solid phase containing amino groups, physical adsorption is sufficient for most cases. Polystyrene appears to be the most stable solid support for this purpose.

### Interaction between Antigens and Antibodies

The antigen-antibody interaction is performed in neutral pH buffers containing reagents for stabilizing enzyme activity as serum albumin, and the incubation time is normally in the range of 1-48 h at 4-37°C. In ELISAs, however, higher temperature and long periods of incubations cause reduction of enzyme activity and elevation of nonspecific binding of the labeled antibody on the solid phase. The interaction between the enzyme-labeled antibody and the antigen should be carefully controlled at a temperature at 20°C or 30°C for 2-4 h.

## Assays

Colorimetric detection is the most commonly used method for the detection of enzyme activity. Fluorometric or chemiluminometric assays are also utilized when high sensitivity is desired because they are often more than 10-fold more sensitive. In fact, fluorometric or chemiluminometric assays can be several thousand times more sensitive when using  $\beta$ -D-galactosidase or alkaline phosphatase as the conjugating enzyme (Table 1).

### Colorimetric Assays

In colorimetric assays, the substrate is converted by the enzyme into a soluble, colored reaction product.

This allows precise determination of the enzyme activity by optical density. For example, peroxidase activity is measured by the reduction of the substrate in the presence of hydrogen peroxide, producing a soluble chromogen that is measured with a spectrophotometer. There are a variety of chromogenic peroxidase substrates that can be used, including the commonly used 1,2-phenylene diamine, 2,2'-azino-di(3-ethyl)benzothiazoline-6-sulphonic acid, 3,3',5,5'-tetramethylbenzidine, and 5-aminosalicylic acid. These give rise to products with a variety of colors, and are therefore measured at various wavelengths. When  $\beta$ -D-galactosidase is used as the conjugating enzyme, 2-nitrophenyl- $\beta$ -D-galactoside is generally used as the substrate, and the colored product is measured at 420 nm. For the colorimetric assays of alkaline phosphatase, 4-nitrophenylphosphate is normally used, and the colored product is measured at 405 nm. In addition, enzymatic recycling of NADP makes the colorimetric assay for alkaline phosphatase as sensitive as fluorometric assays. These colorimetric assay methods are often used for microtiter plate-based ELISAs in combination with an automated spectrophotometer.

### Fluorometric Assays

In general, fluorometric assays are as much as 100- to 1000-fold more sensitive than colorimetric assays (Table 1). This method has, therefore, become essential for the recent development of highly sensitive EIA systems. Spectrofluorometers can detect a minute amount of product when the substrates are not themselves fluorescent or have very low intrinsic fluorescence.

There are number of such artificial substrates that are commercially available for the various enzymes used in EIAs. For example, the fluorometric assay for peroxidase utilizes homovanillic acid, tyramine, 4-hydroxyphenylacetic acid, or 3-(4-hydroxyphenyl)propionic acid (HPPA) as a substrate. While the fluorescence of the product from homovanillic acid is relatively unstable, the products from tyramine, 4-hydroxyphenylacetic acid, and HPPA are fairly stable and are more sensitive. Amongst these three substrates, HPPA is the most effective substrate when a highly sensitive ELISA is sought because it can be used to detect attomoles per assay or even lower levels of antigen or antibody (Table 1).

The activity of  $\beta$ -D-galactosidase can also be assayed fluorometrically, and this generally utilizes 4-methylumbelliferyl- $\beta$ -D-galactoside as the substrate. Enzyme activity produces the fluorescent product 4-methylumbelliferone and  $\beta$ -D-galactoside. The assay system is very stable and there is little interference from blood. In addition, this assay system is

even more sensitive than the fluorometric assays for peroxidase.

The fluorescent assay for alkaline phosphatase takes advantage of a related reagent, 4-methylumbelliferylphosphate. As in the case of  $\beta$ -D-galactosidase, enzyme activity produces the fluorescent product 4-methylumbelliferone. However, 4-methylumbelliferylphosphate has a relatively high intrinsic fluorescence. As a result, the fluorometric alkaline phosphatase assay is not as sensitive as the  $\beta$ -D-galactosidase assay.

### Chemiluminescent Assays

In addition to colorimetric and fluorometric enzyme assays, chemiluminescence can also be used to measure enzyme activities in EIAs. Closely related assays are used for chemiluminescent immunoblotting. For example, peroxidase activity can be measured in the presence of hydrogen peroxide using luminol as a substrate. In this case, the oxidized luminol is in an excited state and releases light, which can then be measured with a luminometer. Alkaline phosphatase can also be measured using the chemiluminescent substrate 3-(2'-spiroadamantane)-4-methoxy-4-(3''-phosphoryloxy)phenyl-1,2-dioxetan. Chemiluminescence permits extremely high sensitivity because the substrate alone produces no light (Table 1). Additional improved chemiluminescent substrates that maintain high stability and light output have been developed for various EIA systems.

### Bioluminescent Assays

Bioluminescent assays are the most sensitive methods for determining enzyme activity (Table 1). There are two types, those that use the firefly luciferin-luciferase system, and those that use a bacterial luciferase system. Of these methods, firefly luciferase has been more extensively studied, and has been utilized in a wide range of scientific fields. This highly sensitive method uses ATP as a substrate to produce light. The bacterial luciferase, usually obtained from *Photobacterium fischeri*, is in a complex with FMN reductase as NAD(P)H:FMN oxidoreductase. In this case, FMN or NADH is used by the enzyme to generate light. A highly sensitive bioluminescence assay has been developed using this system for glucose-6-phosphate dehydrogenase. In this system, glucose-6-phosphate dehydrogenase produces NADH, which then reacts with the bacterial luciferase to produce light. The bioluminescent assay for NADH can be amplified by using a NAD<sup>+</sup> recycling system. Finally,  $\beta$ -D-galactosidase can be measured by a bioluminescent method using 2-nitrophenyl- $\beta$ -D-galactoside as a substrate. In this case, the galactose produced is used by

## Commercially Available EIAs

There are a variety of EIA-based kits for laboratory assays, clinical diagnoses, and environmental and food chemistry. These kits use a combination of homogeneous or heterogeneous methods with competitive or noncompetitive assays (Table 2). For example, determination of several drugs is measured by either homogeneous or competitive EIAs, and several serological markers for diagnosing carcinoma are assessed using ELISA techniques, such as sandwich ELISAs. Determination of antibodies by EIA is also used for the diagnosis of several infectious diseases. Increasingly, these commercially available EIAs are

automated. Because of the sensitivity and selectivity of more recent EIA systems, the use of these techniques will continue to grow throughout the sciences.

### Introduction

Immunoassays represent very selective and sensitive techniques that have found application in several areas such as clinical chemistry, bioanalysis, pharmaceutical analysis, toxicological analysis, and environmental analysis. The first immunoassays developed were radioimmunoassays, which are very sensitive; however, one drawback is the need to work radiochemicals. To circumvent the drawbacks, other labels such as enzymes in combination with photometric measurement have been introduced, however, at the expense of sensitivity. With the development of fluoroimmunoassays (FIAs) an improvement in sensitivity was obtained and by introducing chemiluminescence in immunoassays, a sensitivity equivalent to radioimmunoassays was achieved. In this article, different variations and techniques of luminescence immunoassays are described.

### Theory of Luminescence

Luminescence can be created by photoirradiation, which results in fluorescence, delayed fluorescence, and phosphorescence or by a chemical or biochemical reaction, which produces chemiluminescence and

bioluminescence. Molecules can absorb energy, whereby electrons are excited from the ground state to a higher state. By returning of the electrons to the ground state, the absorbed energy can be turned to radiation as fluorescence. If the transition to the ground state occurs through a metastable triplet state, phosphorescence is observed. Some species, such as lanthanides, show delayed fluorescence, which is a result of two intersystem crossings, the first from the singlet to the triplet and the second from the triplet to the singlet state.

Chemiluminescence can be a result of a chemical or biochemical reaction, an electrochemical process, or a thermal treatment.

## Fluorescence Immunoassays

### Fluorescent Probes

Fluorescent probes used as labels should have high quantum yield, emission wavelengths longer than 500 nm, and Stokes' shifts of over 50 nm. They must possess suitable functional groups such as carboxylic acid, amino, hydroxyl, sulfonic acid residues, acid anhydride, acid chloride, diazonium, isocyanate, isothiocyanate, *N*-hydroxysuccinimide, maleimide.

Commonly used probes are fluorescein derivatives, rhodamine derivatives, polycyclic aromatic hydrocarbons, coumarines, amine reagents such as fluorescamine or NBD-Cl, phycobiliproteins, porphyrins, and metal chelates. The latter may show fluorescence,

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Immunoassays represent very selective and sensitive techniques that have found application in several areas such as clinical chemistry, bioanalysis, pharmaceutical analysis, toxicological analysis, and environmental analysis. The first immunoassays developed were radioimmunoassays, which are very sensitive; however, one drawback is the need to work radiochemicals. To circumvent the drawbacks, other labels such as enzymes in combination with photometric measurement have been introduced, however, at the expense of sensitivity. With the development of fluoroimmunoassays (FIAs) an improvement in sensitivity was obtained and by introducing chemiluminescence in immunoassays, a sensitivity equivalent to radioimmunoassays was achieved. In this article, different variations and techniques of luminescence immunoassays are described.

### Theory of Luminescence

Luminescence can be created by photoirradiation, which results in fluorescence, delayed fluorescence, and phosphorescence or by a chemical or biochemical reaction, which produces chemiluminescence and

bioluminescence. Molecules can absorb energy, whereby electrons are excited from the ground state to a higher state. By returning of the electrons to the ground state, the absorbed energy can be turned to radiation as fluorescence. If the transition to the ground state occurs through a metastable triplet state, phosphorescence is observed. Some species, such as lanthanides, show delayed fluorescence, which is a result of two intersystem crossings, the first from the singlet to the triplet and the second from the triplet to the singlet state.

Chemiluminescence can be a result of a chemical or biochemical reaction, an electrochemical process, or a thermal treatment.

## Fluorescence Immunoassays

### Fluorescent Probes

Fluorescent probes used as labels should have high quantum yield, emission wavelengths longer than 500 nm, and Stokes' shifts of over 50 nm. They must possess suitable functional groups such as carboxylic acid, amino, hydroxyl, sulfonic acid residues, acid anhydride, acid chloride, diazonium, isocyanate, isothiocyanate, *N*-hydroxysuccinimide, maleimide.

Commonly used probes are fluorescein derivatives, rhodamine derivatives, polycyclic aromatic hydrocarbons, coumarines, amine reagents such as fluorescamine or NBD-Cl, phycobiliproteins, porphyrins, and metal chelates. The latter may show fluorescence,

delayed fluorescence, phosphorescence, or energy-transfer fluorescence.

Instead of directly labeling antigens or antibodies, the biotin-avidin (or streptavidin) binding system may be involved. Avidin or streptavidin shows extremely high binding affinity to biotin. One component of the immunoreagents is labeled with biotin and the other with avidin or streptavidin. Thereby direct labeling of proteins with dyes, which may cause inactivation or denaturation if a protein is labeled to a high degree, is circumvented. Streptavidin can bind up to 12 label molecules. This fact results in an enormous amplification of sensitivity. Activated biotinylation reagents are commercially available and there also exist several biotinylated antibodies. Furthermore, labeled streptavidin can be used as a universal reagent for different types of assays.

## Heterogeneous Fluorescence Immunoassays

Heterogeneous immunoassays involve a separation step of the immunocomplex formed between the labeled immunoreagent and the analyte from the free components. Antigens or antibodies are immobilized on a solid phase (columns, coated tubes, microtiter plates, or beads). Mostly polystyrene, polyacryl, agarose, glass, and more recently magnetic beads are used. Heterogeneous assays are usually more sensitive compared to homogeneous assays.

There are different formats of heterogeneous fluorescence immunoassays.

In the competitive format for the determination of haptens, sample haptens, and fluorescent-labeled haptens compete for the binding sites at the immobilized antibodies (in limited amount) (**Scheme 1A**). Fluorescence can be measured either at the solid phase or in solution.

In the two-site assay, the antigens bind to the immobilized antibodies and in the second step labeled antibodies bind to second binding sites of the antigen. This approach is applicable only to large molecules such as proteins (**Scheme 1B**). In another variation the hapten is immobilized and competes with the sample hapten for the reaction with the labeled antibodies (**Scheme 1C**). For the determination of antibodies a so-called sandwich or double antibody assay can be used. The hapten to which the antibodies bind is immobilized and in the second step second labeled antibodies (anti-immunoglobulin), which are directed against the antibodies to be determined, are added (**Scheme 1D**). In another variation, labeled haptens are added after binding of the sample antibody to the immobilized hapten (**Scheme 1E**).

**Scheme 1**

Furthermore, the antibodies directed against the analyte antibodies can also be used in the solid phase (**Scheme 1F**). Instead of these immobilized antibodies, a protein support can also be used for binding the analyte antibodies.

Generally, immunoassays can be classified into limited reagent immunoassay systems (FIA) and excess-reagent immunometric methods (immunofluorometric assay, IFMA).

## Time-Resolved Fluoroimmunoassay

Time-resolved techniques (time-resolved fluoroimmunoassay (TRFIA)) make use of the fact that some compounds have long decay times resulting in phosphorescence or delayed fluorescence (e.g., lanthanide chelate complexes) (**Figure 1**). Apparatus for time-resolved measurements use normally a pulsed excitation source and electronically gated detectors. By this way background fluorescence can be eliminated.

**Figure 1** Principle of time-resolved fluorescence.

On this basis, the dissociation-enhanced lanthanide fluorescence immunoassay was developed. Mostly a two-site assay format is used whereby antibodies are immobilized at microtiter plates and after applying the sample antigen, europium-chelate-labeled antibodies bind to the sample. A commonly used chelating reagent is N1-(*p*-isothiocyanato-benzyl)-diethylene triamine. After the addition of a  $\beta$ -diketone as a dissociation enhancer, at acidic pH, europium is released and fluorescence of Eu is measured. Other TRFIAs use stabilized lanthanide chelates or stable chelates.

## Homogeneous Fluoroimmunoassays

In homogeneous immunoassay techniques no separation step is involved. A characteristic of the homogeneous immunoassay is the modulation of a signal after binding of the labeled component to the partner, forming the immunocomplex.

### Fluorescence Polarization Immunoassay

When a fluorescent dye is excited with polarized light, the fluorescence will also be polarized to a degree that is inversely related to the amount of Brownian motion occurring during the interval between absorption and emission of light. The degree of polarization of the emitted light depends on the lifetime of the excited state and the rotational motion of the molecule. The Brownian motion of larger molecules or molecular complexes (such as antigen-antibody complexes) is reduced. Small molecules show a fast rotation (rotational times of less than 1 ns) whereas large molecules have slow rotation (rotational times of 10–100 ns). Therefore, small fluorescent molecules show minimal emission polarization, while large molecules exhibit high polarization.

**Scheme 2**

The decay time of the fluorophore used as label should be longer than the rotational time of the hapten but shorter than the rotational time of the complex formed. Fluorescein, which has a fluorescence lifetime of 4.5 ns, or rhodamine are the most frequently used fluorophores. For larger antigens, fluorophores with somewhat longer decay times such as Lucifer yellow, dansyl, and umbelliferone derivatives have been tested. In a typical competitive format, the degree of polarization is inversely proportional to the concentration of the analyte.

### Release Fluoroimmunoassay

Release fluoroimmunoassay makes use of an antigen or a hapten, respectively, conjugated through ester or glycosidic bonds to a fluorophore (e.g., a coumarine derivative). The conjugate is nonfluorescent because of quenching effects of the substituent. Hydrolysis of the bond catalyzed by the binding of antibodies releases the fluorophore.

A special variation represents the enzyme-hydrolyzed antibody-protected FIA called substrate-labeled FIA. This approach, which is not to be mixed up with the enzyme-labeled fluoroimmunoassay (ELFIA), is based on cleavage of the glycosidic linkage by the addition of an enzyme, thus releasing the fluorophore (Scheme 2).

Contrary to the ELFIA, the antigen is labeled with a fluorophore and is present in limited concentration, whereas the enzyme is free and used in excess. The analyte and the substrate-labeled hapten compete for the binding sites at the antibody. The conjugate that is bound to the antibody is not accessible for the enzyme.

### Fluorescence Quenching Immunoassay

Indirect quenching FIA, also called fluorescence protection immunoassay, is based on the use of fluorescence-labeled antigens and antibodies directed against the label. When antilabel antibodies bind to the labeled probe, the fluorescence is almost completely quenched. This approach can be either

**Scheme 3**

applied to the determination of antigens (Scheme 3) or in another variation for antibodies.

### Fluorescence Enhancement Immunoassay

Fluorescence enhancement can be based on the change in environment, such as change of polarity, dielectric strength, pH, viscosity, formation of hydrogen bonds. One principle makes use of polarity sensitive fluorescent probes such as dansyl derivatives or anilinonaphthalene sulfonic acid, which show fluorescence enhancement properties upon binding to proteins, e.g., antibodies. The second variation is based on the fact that the fluorescence of a fluorescein-labeled analyte is quenched in the presence of heavy atoms, such as iodine. When the labeled probe binds to the antibody, this quenching is partially reversed.

### Fluorescence Excitation Energy Transfer Immunoassay

This technique uses two different fluorescence labels. A requirement is that the emission spectrum of the donor label overlaps with the excitation spectrum of the acceptor. One fluorophore acting as energy donor is coupled to an antigen, whereas an energy accepting moiety is coupled to the antibody. Upon antigen-antibody binding, energy transfer takes place between the two groups resulting in quenching of the fluorescence of the donor (Scheme 4). The distance between the two molecules has to be less than 10 nm. In a competitive assay an increase in concentration of the analyte leads to a reduction in quenching and an increase in free labeled antigen. Thus, the measured fluorescence intensity is directly proportional to the concentration of the analyte.

As donor-acceptor label pairs, the following have been used: fluorescein-rhodamine, phycoerythrin-pyrene, phycoerythrin-Texas-Red, quinacrine-eosin, fluorescamine-fluorescein, squaric acid-galloycyanine.

### Time-Resolved Fluorescence Immunoassay

Time-resolved fluorescence also allows carrying out homogeneous immunoassays. For this purpose, lanthanide chelates, which are fluorescent in aqueous

**Scheme 4**

solution and do not require the addition of enhancement reagents, are used. For example, a fluorescent europium chelate is coupled to the hapten. After binding to the antibody, fluorescence is quenched. The fluorescence of the free conjugate measured in solution is indirectly proportional to the concentration of the analyte.

### Phase-Resolved Fluoroimmunoassay

Another technique recently applied for immunoassays is phase-resolved fluorometry (frequency-domain fluorometry). This technique is also based on different fluorescence decay times. The decay time can change upon antigen-antibody binding. Instead of pulsed excitation, in this technique the sample is excited with sinusoidally modulated light. With phase-resolved fluorometry, decay times and decay time differences within the range of subnanoseconds can be measured. The phase-resolved technique can be used also for elimination of background noise. This technique, however, has found only a few applications to immunoassays yet.

### Liposome Immunoassay

Liposomes are vesicles produced from phospholipids, cholesterol, fatty acids, etc. In typical liposome immunoassays, a fluorophore, mostly carboxy-fluorescein, is encapsulated in the liposomes. The fluorophore can be released by addition of a lysing component such as serum complement or a surfactant. In several liposome based immunoassay formats the hapten is linked to a cytolytic agent such as mellitin. After the immunoreaction the only free portion of the conjugate is capable of disrupting the liposomes releasing the fluorophore.

### Fluorescence Enzyme Immunoassay

ELFIA make use of enzyme-labeled immunoreagents (antibodies or antigens) and a fluorogenic substrate. The most frequently used enzyme labels are horseradish peroxidase, alkaline phosphatase, and  $\beta$ -D-galactosidase. As coupling procedures mostly the

glutaraldehyde, carbodiimide, or periodate/sodium borohydride methods are used. Instead of direct labeling of the immunoreagents with enzymes, the biotin–streptavidin binding system may be involved. As substrates fluorogenic compounds, which exhibit fluorescence after enzymatic cleavage, are used. Most ELFIA systems are on solid-phase basis (enzyme-linked immunosorbent assay (ELISA)), although a few homogeneous assays (enzyme-multiplied immunoassay technique (EMIT)) have been described. As solid phases polystyrene balls, sepharose microbeads, nitro cellulose membranes, and magnetic particles are used. Homogeneous systems are mainly based on the fact that the antigen–antibody binding inhibits enzyme activity. Generally, heterogenic enzyme immunoassays can be classified into immunoreagent-excess or reagent-limited formats. For the determination of haptens, usually a reagent-limited assay in a competitive mode is applied (Scheme 5).

The substrate is cleaved by the enzyme-labeled hapten in the immunocomplex at the surface. The fluorescence can be measured in solution or at the surface. For the determination of high molecular mass antigens a two-site sandwich assay can be applied. A variation represents the double antibody assay, whereby the second antibody, which is directed against the hapten-specific antibody, is enzyme-labeled. Reagent-excess based assays are mainly used for the determination of antibodies in a noncompetitive format. In Scheme 6, a procedure for an indirect ELISA for the determination of antibodies is described.

Scheme 5

Scheme 6

## Phosphorescence Immunoassay

Erythrosin, eosin, and, more recently, metalloporphyrins have been checked as labels for phosphorescence immunoassays (PIAs). Usually phosphorescence can be measured only at low temperatures (77 K) to avoid molecule collisions. Since this requires a rather complicated instrumental setup, this technique found only rare application. Room temperature phosphorescence in solution is a rather rare phenomenon because of molecule collisions and quenching effects of oxygen. Some compounds such as biphenyl, biacetyl, and bromonaphthalene derivatives show room temperature phosphorescence, providing a deoxygenated solution. The addition of detergents for forming micelles or the inclusion into the cavities of cyclodextrins has been shown to support room temperature phosphorescence. Furthermore, the creation of a rigid state by adsorption or immobilization to a solid matrix has been found to enable room temperature measurements. Room temperature phosphorescence, although a promising approach, has only rarely been applied to immunoassays up to now.

## Chemiluminescence Immunoassay

Chemiluminescence represents emitted light as a result of a certain chemical reaction. Some examples of chemiluminescent reagents are shown in Figure 2. Luminol, acridinium esters, and dioxetanes are the most frequently used labels for chemiluminescence immunoassays (CLIAs).

In several cases the chemiluminescence reaction is initiated by addition of an oxidant such as hydrogen peroxide. Certain stabilized dioxetanes can be chemically cleaved to produce chemiluminescence. Some dioxetane derivatives show thermoluminescence. When simply heated, they are transferred to an excited state and exhibit luminescence. The peroxyoxalate chemiluminescence reaction consists of different steps. The oxalate ester forms upon treatment with hydrogen peroxide an energy-rich dioxetane intermediate, which can transfer its energy to excite an acceptor fluorophore, which emits light. An increase in chemiluminescence emission in the luminol system was achieved by using certain catalysts as ‘enhancers’. Such enhanced chemiluminescence systems use, for example, horseradish peroxidase or certain phenolic molecules as enhancers.

In analogy to FIA, CLIAs have also been developed using chemiluminogenic substrates. Dioxetane derivatives such as adamantyl-1,2-dioxetane phosphate are widely used substrates, which exhibit chemiluminescence upon cleavage by alkaline phosphatase.

**Figure 2** Chemiluminescence reagents.

As in FIAs, different formats such as competitive assays, two-site assays, double antibody assays, are possible in CLIAs also. Both heterogeneous and homogeneous CLIAs have been developed. However,

**Scheme 7**

the benefit of chemiluminescence is the high potential for carrying out homogeneous assays. The main advantage of CLIAs is a significantly higher sensitivity that is comparable to radioimmunoassay or even better. A further advantage is the high selectivity of chemiluminescence. Since the light is produced by a chemical reaction, there is no light scatter from a lamp and there is almost no background noise. According to the selectivity of chemiluminescence there are no interferences from the sample matrix. Moreover, the instrumental setup is very simple and inexpensive.

### Bioluminescence Immunoassay

If luminescence is a result of a biochemical reaction, the principle is called bioluminescence. The most frequently used bioluminescence system is that of the firefly. The enzyme luciferase catalyses the oxidation of luciferin as a substrate in the presence of adenosine triphosphate (ATP) (Scheme 7). Another bioluminescence system makes use of a luciferase from certain marine bacteria. A long-chain aldehyde is oxidized in the presence of luciferase, an oxidoreductase and NAD/NADH. Recently, a photoprotein isolated from the bioluminescent jellyfish *Aequorea victoria*, has been found to be an efficient bioluminescence label for immunoassays.

### Electroluminescence Immunoassay

Chemiluminescence can also be produced by electrochemical oxidation or reduction (electrogenerated chemiluminescence). Ruthenium and osmium chelates show the ability to emit light when undergoing an electrochemical process. Based on this phenomenon, an electroluminescence immunoassay has been developed using a ruthenium(II) tris(bipyridyl) chelate as a label.

## Technologies

### Immunoassays in Tubes, Cuvettes, and Microtiter Plates

For manual handling several test kits are commercially available. Special fluorometers dedicated for immunoassays have been introduced. For enhancement in sensitivity, microfluorometers with laser excitation have been developed. For special purposes fluorescence microscopes and flow-cytometers are available. Microtiter plates are very frequently used in combination

with commercially available kits and fluorometric plate readers are offered by several suppliers.

### Automated Random-Access Instrumentation

In addition to semiautomated systems, several fully automated random-access instrumentation have been developed, which enable a high sample throughput. Both for homogeneous and heterogeneous assays equipments have been developed, whereby for the latter approach frequently magnetic particles are used as carriers. Such random-access instrumentation allows the application of individual analyte and assay types. In addition to instrumentation for FIAs, automate instrumentation for CLIAs are also available. Of course, since such fully automated systems involve roboting operations, they are rather expensive.

### Immunosensors

Most of the fluoroimmunosensors are based on the principle of total internal reflection. When a light beam strikes the interface between two transparent media from the optically denser medium to the optically rarer medium ( $n_1 > n_2$ ), total internal reflection occurs. Upon reflection, some of the light (called evanescent wave) penetrates a fraction of a wavelength beyond the reflecting surface into the rarer medium of a refractive index  $n_2$  (Figure 3).

One type of immunosensors uses a planar waveguide with immobilized antibodies. Excitation is done by the evanescent wave. Alternatively, thin film cuvettes containing waveguides have been developed. A simple approach represents the use of fiber waveguides containing antibodies covalently immobilized

**Figure 3** Principle of total internal reflection:  $n_1$ , optically denser medium;  $n_2$ , optically rarer medium;  $d_P$ , penetration depth.

at the distal end (Figure 4). Such fiber waveguides are very suitable for remote measurements. Another variation consists of a fiber containing a microcuvette at the distal end provided with a dialysis membrane. This setup was used for a homogeneous fluoroimmunoassay applying the fluorescence excitation energy transfer principle involving phycoerythrin-labeled haptens and Texas-red-labeled avidin in combination with biotinylated antibodies.

Although immunosensors represent a promising approach, there are still some problems. The kinetics of antigen-antibody binding is rather slow requiring long incubations. The most important requirement on a sensor is the reversibility. The regeneration of immunosensors still remains a problem. Nonspecific binding and a relatively high background level are further drawbacks. Nevertheless, there is still research work being done to solve these problems.

### Flow-Injection Immunoassay

Flow-injection immunoassay (FIIA) represent a relatively new technique, which involves a flow system for carrying out all steps of the immunoreaction and detection. FIIA systems can be regarded as flow-through sensors. Both homogeneous and heterogeneous FIAs have been developed. In homogeneous assays sample and reagents are mixed by the merging of two streams. A prerequisite is that binding of the antigen to the antibody modulates a standing signal produced by the labeled component. For example, fluorescence excitation energy transfer FIAs and enzyme FIAs have been developed. Heterogeneous FIAs are more frequently used. The essential piece of a heterogeneous FIIA setup is the immunoreactor. It consists of a small column or cell containing immobilized antibodies or antigens, depending on the mode. As carriers, porous glass, polymeric particles, membranes, or, more recently, magnetic particles are used. A typical instrumental setup of a heterogeneous FIIA system is shown in Figure 5.

The simplest setup consists of a peristaltic pump, an injection valve, the immunoreactor, and a detector. For special purposes multichannel pumps and valve switching systems have been developed. Sample and all reagents are injected into a flowing stream and transported to the immunoreactor where binding to the immobilized antibodies (or antigens, respectively) takes place. Detection is carried out either

**Figure 4** Fiber-optic waveguide immunosensor.

**Figure 5** Typical setup for heterogeneous FIIA.

downstream after the immunoreactor or directly at the immunoreactor in a flow-cell.

The main advantages of heterogeneous FIAs over homogeneous assays are the higher sensitivity and selectivity. Usually with heterogeneous FIAs no sample pretreatment is required, since the selective binding in the immunoreactor represents a cleanup and a preconcentration step. Washing of the unbound components is continuous. Furthermore, due to the dynamic system there is very low nonspecific binding. Heterogeneous FIAs show extremely high binding kinetics. There is a high surface to volume ratio in the immunoreactor. Contrary to static systems in FIAs the binding is not based on passive diffusion, the flowing stream actively transports the sample antigens to the binding sites of the immobilized antibodies. All immunoassay formats discussed in the previous paragraphs, including enzyme immunoassays, can be applied in FIAs. Heterogeneous FIAs have been called by some authors as immunochromatographic assays, since the immunoreactor can be regarded as a small affinity chromatographic column. However, this term should be used only if additional chromatographic processes are involved.

Since the instrumental setups for FIAs is very simple, they are predestinated for automation. Several fully automated setups have been developed. The immunoreactors are reusable. After an assay cycle the reactor can be regenerated by a washing step. Up to 500 assays with one immunoreactor have been described. Therefore, the consumption of immuno-reagents is very low. However, of course, the lifetime of the immunoreactor is limited and it has to be exchanged after a series of injections. To overcome this drawback automated membrane or particle exchange devices have been developed. Another alternative is to load the reactor column before every assay with fresh antibodies. Protein A columns, which bind immunoglobulins, have been used for this purpose. The main benefit of FIAs is the speed and flexibility for single assays. The assay times range between 1 and 15 min and the system can be adapted very easily to another type of assay. This is especially of relevance when rapid results are required for different analytes and varying problems. Regarding sample throughput, however, the existing FIIA systems cannot compete with random access carousels.

Besides fluorescence FIAs, chemiluminescence FIAs have also been developed, whereby mainly luminol and acridinium ester were used as chemiluminescence labels. High sensitivity was reported with systems using flow-cells packed with immobilized antibodies or antigens, whereby the luminescence is measured directly at the cell. The assays are carried out by stepwise injection of all components. Detection limits in the attomole range have been reported with such systems. Recently, the stereoselective recognition ability of antibodies raised against one enantiomer has been demonstrated. On this basis an enantioselective chemiluminescence FIIA for amino acids, which allows the detection of less than 0.01% of the unwanted enantiomer, has been developed.

### Sequential-Injection Immunoassay

A variation of flow-injection analysis, sequential-injection analysis (SIA), has recently been introduced. Contrary to flow-injection analysis, where the components are injected into a continuous flowing stream, in SIA injections are done sequentially directly into the reactor/detector system. The instrumental setup usually consists of a syringe pump in combination with an electronically controlled multiport valve. SIA systems have been shown to be more flexible regarding injection volumes and injection times. This technology has been demonstrated to be very efficient for carrying out immunoassays. Both fluorescence and chemiluminescence immunoassays have already been carried out with this technique.

An acid–base titration is a quick and convenient method for the quantitative analysis of substances with acidic or basic properties. Many inorganic and organic acids and bases can be titrated in aqueous media, but others, mainly organic, are insoluble in water. Fortunately, most of them are soluble in organic solvents; hence they are conveniently determined by nonaqueous acid–base titrimetry. Although acid–base titrations can usually be followed potentiometrically, visual endpoint detection is quicker and can be very precise and accurate if the appropriate indicator is chosen.

In aqueous solutions the choice of a suitable indicator for an acid–base titration is usually quite simple. It is only necessary to choose an indicator with a good quality of color change and with a transition pH range that encompasses the pH at the equivalence point of the titration. The quality of color changes and transition pH ranges of many indicators has been determined for aqueous solutions. The use of chemical indicators in most organic solvents can be more complicated and less straightforward than it is in water, but fortunately in recent years the chemistry of nonaqueous solutions has been developed to such an extent that it is possible with a reasonable degree of certainty to predict the behavior of a substance in a given solvent.

To select the most suitable indicator in each solvent in order to titrate a particular acid or base

with good accuracy and precision, it is necessary to know the pK values (see below) or transition pH ranges of a series of indicators with good quality of color change over the whole useful acidity range in each of the selected solvents, but it is also necessary to know the equivalence range of each particular acid titration curve. The discussion of acid–base indicators for titration in nonaqueous solvents in this article is intended to be critical rather than exhaustive and has the aim of solving the main problem of the use of chemical indicators. It therefore focuses on the behavior and choice of indicators at visual titrations in solvents that show practical advantages for acid or base titrations. In this way the most widely used and advantageous solvents for the titration of bases and acids and their mixtures are considered, such as water, acetic acid, acetonitrile, dimethylformamide, isopropyl alcohol, and *t*-butyl alcohol. Obviously, many other solvents have been used in everyday work, but the selected solvents allow particular quantitative problems to be resolved. The use of chemical indicators in mixed solvents is not discussed because there are very few systematic studies of chemical equilibria in these mixed solvents, although some approaches are possible from data on indicator behavior in several pure solvents and taking into account the effect of preferential solution. At the present time, a series of indicators over the whole useful acidity range in each of the chosen solvents has been proposed. Chromatic parameters of transition ranges for each indicator and constants involved in color changes are known. From the solvent selection, from these sets of indicators, and from the equivalence range of each particular titration curve in the solvent chosen it should be possible to select the best fit for the problem at hand.

The use of chemical indicators in mixed solvents is not discussed because there are very few systematic studies of chemical equilibria in these mixed solvents, although some approaches are possible from data on indicator behavior in several pure solvents and taking into account the effect of preferential solution. At the present time, a series of indicators over the whole useful acidity range in each of the chosen solvents has been proposed. Chromatic parameters of transition ranges for each indicator and constants involved in color changes are known. From the solvent selection, from these sets of indicators, and from the equivalence range of each particular titration curve in the solvent chosen it should be possible to select the best fit for the problem at hand.

## Indicator Behavior

Acid–base indicators are generally weak protolytes that change color in solution according to the pH. The acid–base equilibrium of a weak acid type of indicator (HI) in water can be represented as

The acid, HI, and the conjugate base,  $\text{I}^-$ , have different colors. The equilibrium expression for this process is

$$K = \frac{[\text{I}^-][\text{H}_3\text{O}^+]}{[\text{HI}]} \quad [1]$$

This can be expressed in logarithmic form:

$$\text{pH} = \text{p}K + \log \frac{[\text{I}^-]}{[\text{HI}]} \quad [2]$$

From eqn [2], it can be predicted whether the indicator is in its acid or base form, depending on the pH. The last term is the concentration ratio between the base and the acid forms of the indicator, and thus determines the color of the solution.

The human eye has limited sensitivity for distinguishing the components of a mixture of colors. It can be accepted as a working rule, however, that for a mixture of two complementary colors the eye can only detect a change in hue when the concentration

ratio is varied between 10 and 1/10. If these two limiting ratios are substituted into eqn [2], the well-known relation  $\text{pH} = \text{p}K \pm 1$  giving the color transition pH range of the acid–base indicator is obtained. This interval represents the pH region in which the acid–base indicator fully changes its color. Thus the color transition pH range is located in a pH region that depends on the protolysis constant of the indicator. A similar relationship is easily derived for an indicator of the basic type.

However, the transition pH range is often not symmetrically distributed with respect to the pK value of the indicator because the spectral sensitivity of the human eye is not equal throughout the whole visible spectrum. This is why the transition interval is best defined by experiment and often reported in the literature. In Table 1 the transition pH ranges of a wide series of indicators with good quality of the color change that cover the whole useful acidity range in water are presented, together with the pK values. From these values it is seen, as expected, that the interval is not symmetrical around the pK value and also that some indicators require smaller concentration ratio changes and others larger.

If an indicator is to be intelligently and scientifically applied, it is necessary to have quantitative information on the indicator pK values, transition pH range, optimum concentration for the titration arrangement and quality of color changes of the indicator. This is not in itself sufficient – quantitative

**Table 1** pK values, optimum concentrations, and transition pH ranges of indicators in water and in solvents used for the titration of weak acids and their mixtures

Indicator (dissociation model) <sup>b</sup>	Optimum concentration (mol l <sup>-1</sup> )	Water		Isopropyl alcohol		t-Butyl alcohol		Dimethylformamide

information on the equilibria of the titration system is also required to supply the context. The most important part of the titration curve is in the vicinity of the equivalence point, the equivalence region of the titration curve. It is convenient to regard the equivalence region as the part of the curve corresponding to 99.9–100.1% titration. However, in some cases, the equivalence region is considerably shorter than 6 pH units. In such cases, which are not especially rare in analytical practice, it is convenient to accept a less stringent criterion for accuracy, for instance to accept an error of  $\pm 1\%$ . In this case we may conveniently refer to the  $\pm 1\%$  equivalence region.

The equivalence point of the titration has been defined as the point at which the stoichiometric amount of reagent has been added, and the endpoint is the point at which the indicator signal changes. The pH of the equivalence point will be indicated by a suitable indicator. The titration error of the endpoint as visualized by means of indicators consists of three different parts.

(1) The chemical error is caused by the fact that the indicator does not change at exactly the equivalence region, i.e., the pH value of the transition pH range of the indicator differs from the pH values of the equivalence region. (2) The visual discrimination error corresponds to the deviation that originates from the limited capability of the eye in remembering or comparing colors. (3) The indicator error follows from the fact that a certain amount of the titrant will be consumed by the indicator itself.

Errors (2) and (3) are negligibly small in comparison to error (1) and consequently in the selection of a suitable indicator only the magnitude of the chemical error is of great importance. Thus the appropriate acid–base indicator must have its transition pH range within the equivalence region.

Taking into account the wide series of indicators established in water and given in Table 1, Figure 1 shows that the selection of an indicator for the titration of a strong acid with a strong base is not critical when the reagent concentration is  $\sim 0.1 \text{ mol l}^{-1}$ . Thus methyl red, bromothymol blue and phenolphthalein are suitable for detecting the endpoint, because they ensure an accurate analysis with an error less than  $\pm 0.1\%$ ; these limits are shown by horizontal lines in Figure 1 at pH values 4.00 and 10.00. The indicator methyl orange cannot be strongly recommended.

Figure 1 also indicates that the choice of indicator for the titration of a weak acid is more limited than that for a strong acid. The transition pH range of phenolphthalein, which changes color in the basic regions, coincides fairly well with the equivalence region, and hence this indicator ensures an accurate

**Figure 1** Titration curves of  $0.1 \text{ mol l}^{-1}$  acetic acid (—) and  $0.1 \text{ mol l}^{-1}$  hydrochloric acid (---) with  $0.1 \text{ mol l}^{-1}$  sodium hydroxide. Indicator transition pH ranges are indicated for methyl orange (MO), methyl red (MR), bromothymol blue (BrTB), and phenolphthalein (PP).

determination. The other indicators shown in the figure, bromothymol blue, and especially methyl red and methyl orange are not recommended for this determination.

Indicator selection for titration of a base with a strong acid is based upon the same considerations as noted for the titration of an acid with strong base. Clearly, indicators with acidic transition ranges must be employed for weak bases.

From these examples it is obvious that the weaker the protolyte the more difficult it is to determine. The  $pK$  value of the titrated protolyte ( $pK_a$  or  $pK_b$ ) should not be greater than 5–6. Protolytes weaker than this are determined with greater error in aqueous solutions, as the color transition of the indicators is not sharp enough. In such cases nonaqueous solvents should be used.

## Indicators for Titration of Acids in Nonaqueous Solvents

Acid–base indicators for titrations in nonaqueous solvents are normally weak protolytes. For dissociation model I as given in Table 1, the acid–base equilibrium of a weak acid type of indicator in the pure solvent can be represented in water by the following reaction:

HS denotes the solvent,  $\text{H}_2\text{S}^+$  the lyonium and  $\text{I}^-$  the conjugate base of the weak acid indicator HI: HI and  $\text{I}^-$  have different colors. The equilibrium constant of the acid–base interaction can be expressed in the following logarithmic form where  $\gamma_{\text{I}^-}$  represents

the activity coefficient of the chemical species  $I^-$ :

$$pK = pH - \log \frac{[I^-]}{[HI]} - \log \gamma_{I^-} \quad [3]$$

As shown in eqn [3], in nonaqueous solvents activity coefficients must be taken into account to relate the color of an indicator and the pH. Moreover, acid-base indicators may be not only neutral (model I), but also positively or negatively charged. The ionic strength of the solution modifies activity coefficients in a different way for each kind of dissociation model, according to the ionic charge of chemical species.

Many nonaqueous solvents have been proposed as suitable media for the determination of substances with weakly acidic properties or of their mixtures, but only some of them have found widespread use, because of their suitable characteristics and practical advantages. Thus, liquid ammonia and ethylene diamine (1,2-diaminoethane) show unsuitable physical characteristics and high basicity and absorb atmospheric carbon dioxide. Dimethyl sulfoxide and pyridine are unpleasant to use and dangerous in everyday work, although a series of chemical indicators have been established for use in these two solvents. On the other hand, *N,N*-dimethylformamide (DMF) is a very popular solvent for the titration of acids and mixtures of acids, and isopropyl and *t*-butyl alcohols show a large resolution of acid strength and allow to successfully solve acid mixtures.

The series of indicators studied in the use of nonaqueous solvents for the titrations of acids, isopropyl and *t*-butyl alcohols, and dimethylformamide exhibit three more models of acid dissociation shown in the following reactions and equations:

$$pK = pH - \log \frac{[I]}{[HI^+]} + \log \gamma_{HI^+} \quad [4]$$

$$pK = pH - \log \frac{[I^{2-}]}{[HI^-]} - \log \frac{\gamma_{I^{2-}}}{\gamma_{HI^-}} \quad [5]$$

$$pK = pH - \log \frac{[I^+]}{[HI^{2+}]} + \log \frac{\gamma_{HI^{2+}}}{\gamma_{I^+}} \quad [6]$$

$pH_0$ , the pH value at zero ionic strength, is used to refer to the color changes.  $pH_0$  values of the transition pH ranges can be transformed into pH values with knowledge of the model of indicator dissociation and approximative ionic strength value. Table 2 shows the effect of ionic strength on activity coefficients in the solvents considered; owing to the high relative permittivity of DMF,  $\epsilon = 37$ , this effect is much less in DMF than in isopropyl alcohol and *t*-butyl alcohol.

Even at zero ionic strength the  $pK$  values of the indicators do not agree with the pH for the maximum change of color ( $pH_{mcc}$ ), as a result of the different sensitivity of human eye to different colors. The  $pH_{mcc}$  values are displaced, relative to the  $pK$  values, towards pH values at which the concentration of the less intensely colored form is higher.

A series of indicators with good quality of color change have been established that cover the whole useful acidity range in isopropyl alcohol, *t*-butyl alcohol and DMF and are shown in Table 1 together with the dissociation model of the indicator. Table 1 also shows the optimum concentration of the indicator, referred to 10 mm path length, obtained considering the sequence of color changes of the indicators described by the color spaces CIELAB ( $L^*$ ,  $a^*$ ,  $b^*$ ), and CIELUV ( $L^*$ ,  $u^*$ ,  $v^*$ ), recommended by CIE, along with the indicator dissociation constants and their transition pH ranges in each solvent (see below).

To compute the pH of the equivalence point in order to select the most appropriate indicator, a discussion of ionic equilibria in selected solvents is needed. In aqueous solution, calculation of the pH at the equivalence point is quite simple. In the same way, because of the relatively high relative permittivity of DMF, pH values can be calculated on the basis of simple dissociation of

**Table 2** Influence of ionic strength ( $I$ ) on activity coefficient in isopropyl and *t*-butyl alcohols and in dimethylformamide (DMF)

the acid and complete dissociation of the salts, but taking into account the activity coefficients ( $\gamma$ ), which can be calculated by means of the Debye-Hückel equation  $\log \gamma = -A I^{1/2} / (1 + B \alpha I^{1/2})$  where  $A = 1.594$ ,  $B = 0.480 \times 10^{10}$ , and  $\alpha = 5 \times 10^{-10} \text{ m}$  and  $I$  is the ionic strength.

Ionic equilibria in solvents of low relative permittivity have been described in the literature and equations for calculating titration curves have also been proposed. The equations involve the partial dissociation of the acids, bases, and salts in these media, and the effect of the activity coefficients. The equations can be applied to pH and titration curve computation in solvents such as *t*-butyl and isopropyl alcohols, ethylene diamine, pyridine, or tetrahydrofuran.

In solvents of low relative permittivity, because of ion pair formation, the dissociation of an acid (HA) must be considered in two steps:

Usually an overall acidity constant,  $K_a$ , is defined by

$$K_a = \frac{[\text{H}_2\text{S}^+][\text{A}^-]\gamma^2}{[\text{HA}] + [\text{H}_2\text{S}^+\text{A}^-]} \quad \text{[7]}$$

For a base, expressions similar to those for acid can be written:

$$K_b = \frac{[\text{BH}^+][\text{S}^-]\gamma^2}{[\text{B}] + [\text{BH}^+\text{S}^-]} \quad \text{[8]}$$

At the equivalence point, solution equilibria of salts have to be considered. Because salts are constituted of ions, only the dissociation equilibrium must be taken into account. On the basis of equilibrium of

The constant ( $K_{\text{salt}}$ ) can be defined

$$K_{\text{salt}} = \frac{[\text{BH}^+][\text{A}^-]\gamma^2}{[\text{BH}^+\text{A}^-]} \quad \text{[9]}$$

The autoprotolysis constant for the solvent is as given in the following equation:

$$K_{\text{ap}} = [\text{H}_2\text{S}^+][\text{S}^-]\gamma^2 \quad \text{[10]}$$

For computing pH at the equivalence point it is assumed that a few ion pairs and ions can react with the solvent to give the undissociated acidic and basic forms. Total concentrations of acid and base, however, must be the same. The mass

balance is then

$$[\text{HA}] + [\text{H}_2\text{S}^+\text{A}^-] + [\text{A}^-] = [\text{B}] + [\text{BH}^+\text{S}^-] + [\text{BH}^+] \quad \text{[11]}$$

Taking into account that in solvents of low relative permittivity the dissociation constants have low values, the concentrations  $[\text{A}^-]$  and  $[\text{BH}^+]$  can be omitted (moreover, they are nearly the same). Substitution of eqns [7], [8], and [10] into eqn [11] gives

$$([\text{H}_2\text{S}^+]\gamma)^2 = \frac{K_{\text{ap}}K_a}{K_b} \quad \text{[12]}$$

Thus, the pH of the equivalence point of a titration is given by

$$\text{pH}_{\text{ep}} = \frac{1}{2}(\text{p}K_{\text{ap}} + \text{p}K_a - \text{p}K_b) \quad \text{[13]}$$

As can be observed from the practical simplifications presented above, eqn [13] is of general application to any solvent of low relative permittivity if conjugated species and ionic aggregates higher than ion pairs can be neglected, which is the case for isopropyl and *t*-butyl alcohols.

In eqn [13],  $\text{p}K_b$  corresponds to the titrant. The most common titrant solution for the titration of acids in non-aqueous solvents is tetrabutylammonium hydroxide, and stable commercial solutions use methyl or isopropyl alcohol as solvents. The addition of isopropyl alcohol to *t*-butyl alcohol can be neglected because their relative permittivity values are not very different. Methanol addition causes larger variations in  $\text{p}K_a$  values. Thus, the use of titrants without or with low contents of methanol is strongly recommended. For application of eqn [13],  $\text{p}K_b$  values of tetrabutylammonium hydroxide are 2.58 in isopropyl alcohol and 4.91 in *t*-butyl alcohol.

On the other hand, the effects on dissociation equilibria of the presence of small quantities of water in common solvents used in the ordinary analytical laboratory have to be considered. The presence of water decreases the pH scale of the solvent according to the water concentration and should be controlled.

The greatest practical difficulty in the use of the above equations for selection of the most suitable indicators for a particular titration is the lack of  $\text{p}K_a$  values for nonaqueous solvents, although the literature offers some sets of values corresponding to several chemical families of compounds. To determine the resolution of acid strength in nonaqueous solvents  $\text{p}K_a$  values in the organic solvent have been plotted vs  $\text{p}K_a$  in water.  $\text{p}K_a$  values obtained in isopropyl and *t*-butyl alcohols show slopes higher than unity in the families studied. However, it is possible to use these relationships to predict the approximate value of the  $\text{p}K_a$  of the acid to be determined if its  $\text{p}K_a$  value in water is known.

## Indicators for Titration of Bases in Nonaqueous Solvents

It is quite simple with the aid of Table 1 to select the most appropriate indicator for the titration of a basic substance in aqueous solution. However, if the basic substance is not soluble in water or has a weak basic character, anhydrous acetic acid is the solvent of choice for its titration in many cases.

However, as has been shown by Kolthoff and Bruckenstein, there is no direct relationship between pH and the color of an indicator in acetic acid medium. Thus, it is not feasible to specify transition ranges of indicators in terms of pH or millivolts in this solvent. Taking into account that in acetic acid medium the titrant is usually a solution of perchloric acid in acetic acid, since it is the strongest acid in this medium, and moreover is very stable and no changes are caused in the reaction medium, the behavior of acid-base indicators is best represented by the general reaction

The appropriate equilibrium constant is the formation constant of indicator perchlorate  $K_f^{\text{IHClO}_4}$ , which easily relates the color of an indicator in acetic acid medium to the concentration of free perchloric acid,  $c_{\text{HClO}_4}$ :

$$\frac{\sum[\text{IH}^+]}{[\text{I}]} = K_f^{\text{IHClO}_4} c_{\text{HClO}_4} \quad [\text{14}]$$

where  $\sum[\text{IH}^+]/[\text{I}]$  is the ratio between the concentration of the acid forms of the indicator, ionized and dissociated, and the concentration of the basic form of the indicator. As a fair approximation, activities can be substituted by concentrations in acetic acid.

Critical aspects concerning the use of indicators in acetic acid medium have been studied on the basis of color theory and the behavior of the indicator in a titration process of a base B. This behavior is defined by

$$\frac{\sum[\text{IH}^+]}{[\text{I}]} = \frac{K_f^{\text{IHClO}_4}}{K_f^{\text{BHClO}_4}} \cdot \frac{c_{\text{BHClO}_4}}{c_{\text{B}}} \quad [\text{15}]$$

$K_f^{\text{IHClO}_4}$  and  $K_f^{\text{BHClO}_4}$  are the formation constants of indicator perchlorate and base perchlorate, respectively, and  $c_{\text{BHClO}_4}$  and  $c_{\text{B}}$  the concentrations of the species indicated by the subscripts. Hence, the minimum  $K_f^{\text{BHClO}_4}$  value required to titrate a particular base with a maximum error of 1% using the indicator I is given by

$$K_f^{\text{BHClO}_4} \geq \frac{10^2 \times K_f^{\text{IHClO}_4}}{\left( \frac{\sum[\text{IH}^+]}{[\text{I}]} \right)_{\text{mcc}}} \quad [\text{16}]$$

where  $(\sum[\text{IH}^+]/[\text{I}])_{\text{mcc}}$  refers to the point of maximum color change (mcc) in the indicator transition range.  $(\sum[\text{IH}^+]/[\text{I}])_{\text{mcc}}$  can be obtained on the basis of the CIE chromatic theory. From  $K_f^{\text{IHClO}_4}$  and  $(\sum[\text{IH}^+]/[\text{I}])_{\text{mcc}}$  values, the minimum  $K_f^{\text{BHClO}_4}$  required for a particular base to be titrated in acetic acid medium with a particular indicator can be determined; values are shown in Table 3.

Therefore, in order to predict the usefulness of the indicator it is necessary to know the  $K_f^{\text{IHClO}_4}$  and  $(\sum[\text{IH}^+]/[\text{I}])_{\text{mcc}}$  values of an indicator series and to know the  $K_f^{\text{BHClO}_4}$  value of the base to be titrated. There are few  $K_f^{\text{BHClO}_4}$  values available in the literature, but the following equation can be used:

$$K_f^{\text{BHClO}_4} = \frac{K_{\text{HClO}_4} K_{\text{b}}}{K_{\text{BHClO}_4} K_{\text{ap}}} \quad [\text{17}]$$

$K_{\text{ap}} = 10^{-13.9}$  is the autoprotolysis constant of acetic acid and  $K_{\text{HClO}_4} = 10^{-4.87}$ ,  $K_{\text{b}}$  and  $K_f^{\text{BHClO}_4}$  are the dissociation constants of perchloric acid, base, and base perchlorate salt defined in eqns [7], [8], and [9], respectively.

$K_{\text{b}}$  and  $K_{\text{BHClO}_4}$  for a great number of significant bases are given in the literature. Moreover,  $K_{\text{b}}$  and  $K_{\text{BHClO}_4}$  values of nonreferenced bases can also be estimated from potentiometric curves that are commonly found in the literature. Furthermore, the majority of  $K_{\text{BHClO}_4}$  values determined for different bases fall between  $10^{-5}$  and  $10^{-6}$  and the decrease in the dissociation degree of bases in acetic acid medium parallels that in water. Bases stronger than about  $\text{p}K_{\text{a}} = 5$  in water are leveled in acetic acid with a  $\log K_f^{\text{BHClO}_4}$  value of  $\sim 9$ . So, their titration curves in acetic acid are very similar. Also  $\text{p}K_{\text{a}}$  values in water must be equal to or greater than 1.5 to titrate the base in acetic acid medium.

On the other hand, despite interesting studies of visual titrations in acetic acid medium, in actual practice, crystal violet and methyl violet, which exhibit identical color changes, are by far the most widely used indicators. This is probably because their two chromatic transitions in acetic acid cover an unusually large potential range of  $\sim 200$  or  $300$  mV. However, in titrations of bases with  $\text{p}K_{\text{b}} > 6.8$ , the endpoint of crystal violet is assigned to a color that is not in agreement with the complete chromatic transition. Consequently, the visual endpoint location is difficult and depends on the base to be titrated and also on its concentration.

The most appropriate indicator in each case for the titrations in acetic acid medium that guarantees accuracy and precision can be selected with the aid of Table 3. Thus, the concentration of perchloric acid at

**Table 3**  $K_f^{\text{HClO}_4}$ ,  $\sum([\text{IH}^+]/[\text{I}])_{\text{mcc}}$ ,  $(\log K_f^{\text{BHClO}_4})_{\text{min}}$  and transition  $\text{pO}_{\text{HClO}_4}$  range values in anhydrous acetic acid;  $\text{pK}$  values and transition  $\text{pH}$  range in acetonitrile; and optimum concentration of indicators used for the titration of weak bases and their mixtures

Indicator (dissociation model in acetonitrile)	Optimum concentration ( $\text{mol l}^{-1}$ )	$\log K_f^{\text{HClO}_4}$	Transition $\text{pO}_{\text{HClO}_4}$	Acetic acid		Acetonitrile

Neutral red(V)	$4 \times 10^{-5}$					4.67	3.4–6.4

the equivalence point of a titration in acetic acid medium is given by

$$c_{\text{HClO}_4} = \left( \frac{c_{\text{BHClO}_4}}{K_f^{\text{BHClO}_4}} \right)^{1/2} \quad [18]$$

$c_{\text{BHClO}_4}$  is the concentration of the base perchlorate at the equivalence point that corresponds to the initial concentration of the base and the indicator series in Table 3 also provides transition ranges in terms of  $\text{pO}_{\text{HClO}_4}$ .

Thus, for a titration of a base B, it becomes easy to estimate the  $c_{\text{HClO}_4}$  value of the equivalence point and according to this value to select the most suitable indicator of the series mentioned.

Table 3 shows optimum concentrations of the indicators referred to 10 mm path length of solution.  $(\sum[\text{IH}^+]/[\text{I}])_{\text{mcc}}$  refers to the point of maximum color change in the indicator range and transition  $\text{pO}_{\text{HClO}_4}$  ranges for a series of indicators in acetic acid medium that show a good quality of color change in this medium. All these values are obtained on the basis of chromatic theory of the CIE.

On the other hand, although for many years acetic acid has been the most popular solvent for titration of bases, acetonitrile – which is a considerably weaker base and much weaker acid than water – shows a greater  $\text{pH}$  jump in the titration curves of bases. Acetonitrile solvation of anions is less than that of cations and, from an analytical viewpoint, conjugation is negligible for bases. This fact makes acetonitrile very suitable for the determination of very weak bases and mixtures of bases. In this medium many workers have used a solution of perchloric acid in anhydrous acetic acid as a titrant. However, for the differentiating titration of two or more bases of different strengths, it is necessary to avoid the leveling effect of acetic acid, whose presence decreases the potential break in acetonitrile, especially in the basic side. A solution of perchloric acid monohydrate in nitromethane is stable and very suitable for titrations in acetonitrile.

The precise interpretation of potentiometric titration curves for base titrations in acetonitrile and the calculation of the  $\text{pH}$  changes near the equivalence point require only knowledge of the dissociation constants,  $K_{\text{HB}^+}$ , of the protonated bases to be titrated, because in solvents of relatively high relative permittivity (such as acetonitrile) perchloric acid and perchlorate salts can be considered to be completely dissociated. The well-known expression commonly used is

$$K_{\text{HB}^+} = \frac{a_{\text{H}^+}[\text{B}]\gamma_{\text{B}}}{[\text{HB}^+]\gamma_{\text{HB}^+}} \quad [19]$$

The neutralization curves of such bases or their mixtures and the change in pH near the equivalence point can then be calculated as they are in water.

The dissociation constants of the protonated forms of a large number of bases are known. A plot of  $pK_{HB^+}$  values of bases in acetonitrile versus the  $pK_{HB^+}$  values in water is roughly linear, with a slope of 1.06. This low value of resolution of acid strength is in agreement with the observation that aprotic solvents do not much improve the resolution of acid strength of cationic acids, in contrast to the case for uncharged acids.

Thus, it is possible to calculate the neutralization curves of bases in acetonitrile and it is also possible to predict which indicator will give a sharp color change at the equivalence range when the  $pK$  values or transition pH ranges of a series of indicator with good quality of color change are known (Table 3).

Table 3 shows a series of indicators in acetonitrile medium, with a pronounced color change, covering the more useful acidity range in acetonitrile. This indicator series takes into account different kinds of equilibria, as described for indicators used in titration of acids, and refers to the transition ranges of pH at zero ionic strength in the same way as those for alcoholic and DMF media. The influence of ionic strength on activity coefficients in acetonitrile is very similar to that in DMF given in Table 2. Because of the high relative permittivity of acetonitrile ( $\epsilon = 36$ ), the activity coefficient values have less influence than in other solvents.

In Table 3, optimum concentration, dissociation model,  $pK$  values and transition pH ranges for the indicator series in acetonitrile are given. From this table and constants of the base to be titrated, it is simple to select the best indicator for a specific titration in acetonitrile medium in the same way as in water, but taking into account the activity coefficients, which can be calculated by the following reduced Debye-Hückel equation, where  $z_i$  is the ionic charge,  $\epsilon$  is the relative permittivity and  $I$  is the ionic strength:

$$\log \gamma_{HB^+} = -355z_i^2 \epsilon^{3/2} I^{1/2} \quad [20]$$

## Quality of Color Change of Indicators

Another critical aspect that must be considered for selection of a suitable indicator for an acid-base titration in a given solvent is the quality of color change of the indicator in this solvent. The quality of color change is related to the sharpness of the chromatic transition and to the sensitivity of the color change.

The color change qualities of a series of commercially available indicators with pronounced color change have been studied in several nonaqueous solvents such as acetic acid, acetonitrile, dimethylformamide, and isopropyl and *t*-butyl alcohols.

To establish the color change quality of an indicator on an objective basis, the color changes have to be characterized by chromatic parameters. The sequence of color changes of indicators can be described for both CIE and complementary chromaticity systems from the experimental values obtained in indicator solutions, by continuous measurement of the absorbance values at 10 nm intervals between 380 and 770 nm over the pH range of the color change of the indicator, and simultaneously by potentiometric measurement.

The color transitions of series of indicators in the solvents discussed above have been described by the traditional 1931 CIE system ( $x, y, Y$ ) or by the latest color spaces CIELAB ( $L^*, a^*, b^*$ ), and CIELUV ( $L^*, u^*, v^*$ ), recommended by the CIE.

The CIELAB and CIELUV systems can be used advantageously to calculate color differences  $\Delta E$  where  $L^*, a^*, b^*$  and  $L^*, u^*, v^*$  are the chromaticity coordinates of the color points:

$$\Delta E = [(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{1/2} \quad [21]$$

$$\Delta E = [(\Delta L^*)^2 + (\Delta u^*)^2 + (\Delta v^*)^2]^{1/2} \quad [22]$$

The complementary chromaticity coordinates ( $Q_x, Q_y$ ), which are color physical constants, have also been used to describe the color sequences of indicators (Figure 2). The plots of  $Q_x, Q_y$  coordinates of the color sequences of indicators are intersecting straight lines, denoting mixtures of two pure colored species in all instances. Thus, for example, the fact that crystal violet in acetic acid medium produces two linear

Neutral red(IV)										50	1.9	16.9

segments shows the presence of two different equilibria involving a particular color change, each first from violet to blue and then to yellow, but only the first can be observed easily and permits results with the desired level of accuracy and precision to be obtained.

The color distribution in these chromaticity diagrams is not uniform, however, and it does not allow the direct evaluation of the quality of color changes. As a consequence, it is not possible to compare the qualities of color changes of the indicators, because the same distance has different physical meanings in different areas of the diagram. Further, complementary chromaticity data give no information about the ideal concentration for the use of the indicators.

The method of Kotrlý and Vytras has been used to obtain the optimum concentrations of the indicators for the titration arrangement used. They pointed out that the spatial transition curve of a color change can be divided into small segments related to a suitable variable, usually pH or the concentration of free perchloric acid,  $c_{HClO_4}$ , in acetic acid medium. The ratio  $\Delta pH/\Delta E$  or  $\Delta p_{HClO_4}/\Delta E$  was taken as an index of color change perceptibility.

The minimum of the graph of this index versus  $\log(c/c_{ref})$  gives the optimum indicator concentration;  $c_{ref}$  is the reference experimental value of the indicator concentration,  $c$  is the indicator concentration and  $\Delta E$  is the total difference between two colors, calculated by using the CIELAB or CIELUV systems. The results obtained for the series of indicators studied are summarized in Tables 1 and 3.

To describe objectively the quality of color changes of the indicators, a modification of the method of Bhuchar and Agrawal, based on a plot of  $\Delta E/\Delta pH$  or  $\Delta E/\Delta p_{HClO_4}$  (the specific color discrimination (SCD) values) against a suitable variable, pH or  $p_{HClO_4}$ , has been used, using indicator solutions at the optimum concentration.

In this plot, the bandwidth of each peak is the transition range of the indicators in terms of pH or  $p_{HClO_4}$  in acetic acid medium, and the pH or  $p_{HClO_4}$  value at the maximum is the value for the maximum color change ( $(pH)_{mcc}$  or  $(p_{HClO_4})_{mcc}$ ). The half-bandwidth [ $(\Delta pH)_{1/2SCD}$  or  $(\Delta p_{HClO_4})_{1/2SCD}$ ] is also related to the sharpness of the chromatic transition, and the maximum of each peak (in SCD units) is taken as the sensitivity of the color change. The data obtained for the series of indicators studied in the different media are summarized in Tables 1, 3, and 4. The results obtained in acetic acid medium using CIELAB system are shown in Figure 3, which shows the usefulness of all the indicators studied in this medium and the great color change sensitivity of malachite green, brilliant green and *p*-naphtholbenzein. From Figure 3, and Tables 1, 3, and 4 it is easy to select the best indicator for a specific titration.

## Types of Acid–Base Indicators

Most acid–base indicators are dyestuffs from four classes of organic compounds: azo dyes, phthaleins, sulfonphthaleins, and triphenylmethane dyes.

**Figure 3** Changes of SCD values with  $p\text{CHClO}_4$  in acetic acid medium. QR, quinaldine red; RD, 4'-dimethylaminobenzalrhodanine; MY, metanil yellow; TR, tropaeolin OO; BG, brilliant green; CV, crystal violet; MG, malachite green; S, sudan III; PNB, *p*-naphtholbenzein; BN, nile blue.

### Azo Dyes

The classical azo indicators exhibit a color change from red to yellow with increasing basicity. The most commonly encountered examples are methyl orange and methyl red. The behavior of the former is described by reaction [X].

Methyl red is similar to methyl orange except that the sulfonic acid group is replaced by a carboxylic acid group. Other azo dyes commonly used in nonaqueous solvents are azo violet and tropaeolin OO.

### Phthaleins

Most phthalein indicators are colorless in moderately acidic solutions and exhibit a variety of colors in alkaline media. The structural changes causing the color changes can be illustrated with the example of phenolphthalein, which is widely used in analytical practice (reaction [XI]).

Loss of the first proton does not cause any great structural change in the molecule. With the removal of the second, however, a quinonoid structure is obtained, a structure that is often associated with color. At very high pH values phenolphthalein again changes to a colorless form. The other phthalein indicators differ only in that the phenolic rings contain additional functional groups: thymolphthalein, for example, has two alkyl groups on each ring. The basic structural alterations associated with the color changes of this indicator are similar to those of phenolphthalein.

### Sulfonophthaleins

The sulfonophthalein indicators are increasingly used in aqueous and nonaqueous solutions because

of their sharp color changes and great color intensity. Many of the sulfonophthaleins exhibit two useful color change ranges; one occurs in rather acidic solutions and the other in neutral or moderately basic media. The parent compound of this group is phenol red (phenol-sulfonophthalein). The principal equilibria of this compound are shown in reaction [XII].

Thus, phenol red is a bifunctional indicator with two transition pH ranges. However, only the second of the two color changes, occurring in the pH range between 6.4 and 8.2, is useful. Substitution of halogen or alkyl groups for the hydrogen in the phenolic rings of the parent compound yields sulfonophthaleins that differ in color and transition pH ranges. The most important are bromocresol green, bromocresol purple, bromothymol blue, cresol blue, phenol red, *m*-cresol purple, and thymol blue.

### Triphenylmethane Dyes

The most important indicators of this group are crystal violet, malachite green, and methyl violet. These compounds act like very weak bases and play only an inferior role as indicators in titrations in aqueous solution. However, these indicators are important for the endpoint indication of titrations in nonaqueous media. The equilibrium relations of crystal violet are shown in reaction [XIII].

### Introduction

The pH of an aqueous solution gives a measure of the concentration of solvated protons present. Its oxidation–reduction potential,  $E$  (redox potential), is a measure of its ability to act as an oxidizing or reducing agent. Acid–base indicators are used to give a colorimetric estimation of pH. In a similar way, redox indicators give a colorimetric estimation of the redox potential of a solution. Redox indicators are organic compounds, or metal chelate complexes, that can undergo redox reactions. The oxidized and reduced forms of the indicator have different colors. Whereas pH measures the concentration of solvated protons present but does not tell us about the intrinsic acidity of chemical species present in solution, electrode potentials inform us about the intrinsic oxidizing power of the species present but give no

information on their concentration. By the addition of a suitable amount of redox indicator to a solution, its redox potential can be measured as an alternative to using redox electrodes.

Redox indicators have been widely used to detect the endpoint of titrimetric redox analyses. Potentiometric detection of endpoints has now largely replaced the use of indicators, but redox indicators are still in use because of their simplicity. Redox indicators can be used to assess redox potentials in many redox systems where visual rather than electrical measurements can sometimes be more helpful. Recent applications of redox indicators include flow-injection analysis with colorimetric monitoring, or the measurement of electrode potentials of solutions using an immobilized redox indicator on the end of a fiber-optic probe. In studies of the metabolism of cells, redox indicators with their color or fluorescence changes are sometimes more convenient than potentiometry. Redox indicators suffer from their dependence on pH changes, and there is not yet a ‘universal redox indicator’ that can show the redox potential of a solution over a wide range of potentials

### Introduction

The pH of an aqueous solution gives a measure of the concentration of solvated protons present. Its oxidation–reduction potential,  $E$  (redox potential), is a measure of its ability to act as an oxidizing or reducing agent. Acid–base indicators are used to give a colorimetric estimation of pH. In a similar way, redox indicators give a colorimetric estimation of the redox potential of a solution. Redox indicators are organic compounds, or metal chelate complexes, that can undergo redox reactions. The oxidized and reduced forms of the indicator have different colors. Whereas pH measures the concentration of solvated protons present but does not tell us about the intrinsic acidity of chemical species present in solution, electrode potentials inform us about the intrinsic oxidizing power of the species present but give no

information on their concentration. By the addition of a suitable amount of redox indicator to a solution, its redox potential can be measured as an alternative to using redox electrodes.

Redox indicators have been widely used to detect the endpoint of titrimetric redox analyses. Potentiometric detection of endpoints has now largely replaced the use of indicators, but redox indicators are still in use because of their simplicity. Redox indicators can be used to assess redox potentials in many redox systems where visual rather than electrical measurements can sometimes be more helpful. Recent applications of redox indicators include flow-injection analysis with colorimetric monitoring, or the measurement of electrode potentials of solutions using an immobilized redox indicator on the end of a fiber-optic probe. In studies of the metabolism of cells, redox indicators with their color or fluorescence changes are sometimes more convenient than potentiometry. Redox indicators suffer from their dependence on pH changes, and there is not yet a ‘universal redox indicator’ that can show the redox potential of a solution over a wide range of potentials

analogous to the way in which a 'universal pH indicator' covers a wide range of pH.

In this article, the physicochemical principles of redox reactions are outlined as a preliminary to an account of the function of redox indicators. Redox indicators are sensitive to the pH of a solution as well as to its redox potential, and the nature of this dependence is described. There then follows a discussion of the various types of redox indicators used, and Table 1 gives details of a range of these indicators.

## Oxidation Potentials in Solution

### Nernst Equation and Standard Hydrogen Electrode

The redox potential of a solution,  $E$ , can be written for each component undergoing a redox reaction [I]

using the Nernst equation [1]:

$$E = E^0 + \frac{RT}{nF} \ln \left( \frac{a_{\text{Ox}}}{a_{\text{Red}}} \right) \quad [1]$$

where  $a_{\text{Red}}$  and  $a_{\text{Ox}}$  are the activities of the oxidized and reduced species, respectively, and  $E^0$  is the standard electrode potential. As the activities are usually not known accurately, but concentrations of species are known, the modified Nernst equation

$$E = E'_0 + \frac{RT}{nF} \ln \left( \frac{[\text{Ox}]}{[\text{Red}]} \right) \quad [2]$$

is normally used, where the formal potential  $E'_0$  is the potential of a solution containing equal concentrations (not necessarily of unit molarity) of the oxidized and reduced species, under specified conditions

of other electrolytes present. In order to compare redox indicators easily, the values of formal potentials at pH 0 ( $1 \text{ mol l}^{-1}$  acid) are usually given. For accurate work, it is necessary to check which acid has been used for the measurement of  $E'_0$ . Formal potentials vary with pH and the symbol  $E'_m$  is used to denote the formal potential measured at pH  $a$ .

### Variation in Oxidation Potential as an Oxidizing Agent Reacts with a Reducing Agent

When a one-electron oxidant such as  $\text{Ce}^{4+}$  is added to a one-electron reductant such as  $\text{Fe}^{2+}$  at pH 0, the electrode potential,  $E$ , of the system changes during the addition as shown in Figure 1. When an amount of  $\text{Ce}^{4+}$  has been added equal to half the number of moles of  $\text{Fe}^{2+}$ , half the  $\text{Fe}^{2+}$  has been oxidized to

**Figure 1** Variation of electrode potential  $E$  as  $\text{Ce}^{4+}$  is added to  $\text{Fe}^{2+}$  at pH 0. For significance of A, B, and C, see text.

**Table 1** Selected redox indicators

Indicator	$E'_0$ (V)	$E'_m$ (V) <sup>a</sup>	Type	Color of oxidized form <sup>b</sup>	Color of reduced form <sup>b</sup>	Useful pH
Safranin T	0.24	−0.29	Azine	Magenta	Colorless	1–12
Phenosafranin	0.28	−0.25	Azine	Magenta	Colorless	1–11
Indigo disulfonic acid (indigo carmine)	0.29	−0.12	Indigo	Blue	Colorless	<9
Indigo tetrasulfonic acid	0.36	−0.05	Indigo	Blue	Colorless	<9
Methylene blue	0.53	0.01	Thiazine	Blue	Colorless	1–13
Brilliant cresyl blue	0.58	0.05	Phenoxazine	Blue	Colorless	0–11
2,6-Dichloro-indophenol	0.67	0.22	Indophenol	Blue	Colorless	6–11
Bindshedler's green	0.68	0.22	Indamine	Green	Orange	2–9.5
Phenol blue	0.68	0.22	Aminoindophenol	Blue	Colorless	1–12.5
Variamine blue	0.71	0.31	Variamine	Blue	Colorless	1.5–6.3
Diphenylamine sulfonic acid	0.85	–	Diphenylamine	Red-violet	Colorless	<1
Tris(bipyridyl)iron	1.03	1.10	Chelate	Violet	Green	<7
Ferriin	1.11	1.12	Chelate	Blue	Red	<7

<sup>a</sup>Where measured.

<sup>b</sup>Colors often depend on pH of solutions.

$\text{Fe}^{3+}$ , and the potential (A in Figure 1) is the  $E'_0$  of  $\text{Fe}^{3+}/\text{Fe}^{2+}$ . When all  $\text{Fe}^{2+}$  has been oxidized to  $\text{Fe}^{3+}$ , the potential changes rapidly (B in Figure 1). If a further amount of  $\text{Ce}^{4+}$  equal to half the number of moles of  $\text{Fe}^{2+}$  is added, the potential reaches the  $E'_0$  of  $\text{Ce}^{4+}/\text{Ce}^{3+}$  (C in Figure 1).

### What a Redox Indicator is Required to Do

For titrations of reductants with oxidants, a redox indicator is required to indicate when the potential of the solution has reached that at equivalence (B in Figure 1). For an observer to see that an indicator has fully changed color, it is generally taken that the ratio  $[\text{Ind}_{\text{red}}]/[\text{Ind}_{\text{ox}}]$  needs to change from 1:10 to 10:1. Application of the Nernst equation shows that this involves a change of potential of  $\sim 0.12/n_{\text{ind}}$  V, that is 120 mV for a one-electron indicator or 60 mV for a two-electron indicator at room temperature.

### Complications Arising out of pH Changes

If the redox equation for a reaction involves hydrogen ions, the potential of the solution will depend on pH as well as on the concentrations of the oxidized and reduced species.

For instance, for the reduction of permanganate (reaction [II])

the redox potential depends on the eighth power of the hydrogen ion concentration. The Nernst equation is then

$$E = E'_0 + \frac{RT}{nF} \ln \left( \frac{[\text{MnO}_4^-]}{[\text{Mn}^{2+}][\text{H}^+]^8} \right) \quad [3]$$

Changes in pH may also change the speciation of the reductants or oxidants as protonation changes.

### Basic Features of Redox Indicators

A redox indicator is a substance that undergoes redox reactions as in reaction [III], where the oxidized and reduced forms have different colors:

#### How Reduced and Oxidized Forms Have Different Colors

The chemical structures of the oxidized and reduced forms of an indicator are different. Many organic redox indicators contain aromatic rings, and there are large differences in ring conjugation between the oxidized and reduced forms, for instance, oxidized (blue color) and reduced (colorless) methylene blue ((1) and (2)).

Metal chelate redox indicators have the metal in different oxidation states in the two forms, and the colors consequently reflect the different numbers of d electrons involved in the metal–ligand interactions.

### Simplest Example – No Dependence on pH

The indicator tris(1,10-phenanthroline)iron(II), sometimes called ferroin (3), has an  $E'_0$  value of 1.06 V.

The redox reaction [IV]

does not involve hydrogen ions, and the formal potential,  $E_m$ , of the indicator is largely independent of pH from neutral solution up to  $5 \text{ mol l}^{-1} \text{ H}_2\text{SO}_4$ . The color change between reduced and oxidized forms will take place at an electrode potential largely independent of pH.

### Dependence on pH When the Redox Equilibrium Contains an $\text{H}^+$ Term

For the majority of redox indicators, the redox reaction involves hydrogen ions, and consequently the potential when  $[\text{Ind}_{\text{red}}]/[\text{Ind}_{\text{ox}}]$  is unity varies with pH. Thus for the indicator methylene blue, the redox reaction may be written as

and the Nernst equation is given by

$$E = E'_0 + \frac{RT}{2F} \ln \frac{[\text{Meblue}_{\text{oxidized}}][\text{H}^+]}{[\text{Meblue}_{\text{reduced}}]} \quad [4]$$

Hydrogen ions will alter the potential at which  $[\text{Meblue}_{\text{(oxidized)}}] = [\text{Meblue}_{\text{(reduced)}}]$ , and so the indicator will need to be used under defined conditions of acid strength if it is being used to measure electrode potentials.

### Further pH Complications as Oxidized and Reduced Forms May Each Involve Protonation or Deprotonation of Suitable Groups

Most organic redox indicators contain groups that can ionize (e.g., OH, NH) or can be protonated (e.g., amine N, ketonic O). As pH is changed, the speciation of the oxidized and reduced form of the indicator can change, depending upon the  $\text{p}K_{\text{a}}$  values of these acid/base groups. Thus for variamine blue, there are two nitrogen atoms that can be protonated or not. For the reduced indicator, any of (4–6) can be present.

For the oxidized form, an analogous three species are possible. Their relative concentrations are determined by the pH of the medium and the  $\text{p}K_{\text{a}}$  values of the protonations.

**Combination of pH-related effects** The combination of pH effects described above results in a complex curve of  $E_{\text{m}}$  against pH. In  $1 \text{ mol l}^{-1}$  acid, the reduced and oxidized forms of the indicator both contain protonated nitrogen atoms. The redox equation for the

indicator in acidic medium may be written as

If no other effects were present, the presence of the hydrogen ions in the redox equation would change the formal redox potential,  $E_{\text{m}}$ , by 60 mV for each pH unit increase. However, as pH is raised, the secondary amine nitrogen deprotonates in both the oxidized and reduced forms, until at about pH 9 both oxidized and reduced forms have lost one proton, and the redox equilibrium is

Further basification causes the primary amine nitrogen to deprotonate and the redox equilibrium is

If the  $\text{p}K_{\text{a}}$  values for the secondary amine protonation are  $\text{p}K_{\text{red1}}$  and  $\text{p}K_{\text{ox1}}$  respectively for the reduced and oxidized forms, and the  $\text{p}K_{\text{a}}$  values for the

primary amine protonation are  $pK_{\text{red2}}$  and  $pK_{\text{ox2}}$  respectively, it can be shown that the electrode potential of a variamine blue solution is related to the formal potential,  $E'_0$ , by

$$E_m = E'_0 + \frac{RT}{2F} \ln \frac{[\text{H}^+]^4 + K_{\text{red1}}[\text{H}^+]^3 + K_{\text{red1}}K_{\text{red2}}[\text{H}^+]^2}{[\text{H}^+]^2 + K_{\text{ox1}}[\text{H}^+] + K_{\text{ox1}}K_{\text{ox2}}} \quad [5]$$

Complex expressions of this type can be deduced for all redox indicators that have ionizable protons. In practice, it is often easier to measure how  $E_m$  varies with pH than to calculate it.

**Reversibility of redox indicators** For a reversible redox indicator, the addition of a suitable oxidant oxidizes its reduced form to its oxidized form. Then the addition of a suitable reductant will reduce it back again. Many organic compounds undergo an irreversible color change on oxidation. The addition of reductant does not give the original reduced indicator. Such compounds have been used as redox indicators in titrimetry, but definition of their formal potential is impossible. However, the potential when they are oxidized can be determined roughly. Such indicators may prove useful in titrations if no reversible indicator with suitable  $E_m$  or suitable color change can be found.

## Classes of Redox Indicators

### Metal Chelates

Transition metal chelate complexes of ligands containing the  $\alpha,\alpha'$ -diimine grouping (7) are numerous, and those of iron, ruthenium, and osmium have successfully been used as redox indicators. The tris(1,10-phenanthroline)iron complex (ferroin) is the most familiar. The iron(II) derivative is orange-red ( $\epsilon = 11\,100 \text{ mol}^{-1} \text{ l cm}^{-1}$  at 510 nm) and the iron(III) derivative is pale blue ( $\epsilon = 900 \text{ mol}^{-1} \text{ l cm}^{-1}$  at 590 nm), so a large color change takes place when the indicator undergoes a redox reaction. The formal potential,  $E'_0$ , is 1.06 V in  $1 \text{ mol l}^{-1} \text{ H}_2\text{SO}_4$ . Changes in substituent on the phenanthroline rings alter  $E'_0$  a little. For example, the 5-nitro derivative has  $E'_0$  at 1.25 V whereas the 3,4,6,7-tetramethyl derivative has  $E'_0$  at 0.87 V. Potentials of ruthenium analogs are  $\sim 0.1 \text{ V}$  higher, and those of osmium analogs are 0.2 V higher. The ruthenium derivatives are fluorescent (see later).

Bipyridyl complexes are less resistant to hydrolysis in acidic solution, and have lower  $E'_0$  values. For

example, the tris(2,2'-bipyridyl) complex of iron has an  $E'_0$  of 1.06 V.

### Diphenylamine and Its Derivatives

Diphenylamine and its derivatives have been successfully used as redox indicators for many years. The precise detail of how these indicators work is still under discussion. The conventional explanation is that colorless diphenylamine is irreversibly oxidized to colorless diphenylbenzidine in a two-electron reaction:

Diphenylbenzidine is then able to act as a two-electron reversible redox indicator to give purple-violet diphenylbenzidine violet:

Unfortunately diphenylamine is not very soluble in water, so more soluble derivatives are used such as the popular 4-sulfonic acid derivative (8).

The formal potentials of diphenylamine derivatives are in the range 0.7–1.1 V.

### Triphenylmethane Dyes

These are one-electron redox indicators that are based on substituted triphenylmethane,  $\text{Ar}_3\text{CH}$ . The basic redox reaction is

The oxidized forms,  $\text{Ar}_3\text{C}^\bullet$ , are radicals and their colors arise from electron delocalization over the three aromatic rings. The aromatic rings contain at least one (and often two or more) *para*-amino group or *para*-hydroxy group, which upon oxidation become double-bonded imine or ketone functions. Malachite green (9) and Victoria blue B (10) are typical examples.  $E'_0$  values for many triphenylmethyl dyes are  $\sim 1$  V in acidic solution. In their reduced forms, most are blue or purple in neutral solution, changing to green or yellow on acidification, and give intense orange-red colors on oxidation.

### Indigo Dyes

Indigo is the basis of intense dyestuffs, and can be made water soluble by the incorporation of sulfonic acid substituents. Indigo sulfonic acids are two-electron reversible redox indicators, with formal

potentials  $E'_0$  ranging from 0.26 to 0.41 V. The reduced forms are pale yellow or colorless, while the oxidized forms range from deep blue to reddish blue depending upon the number of sulfonic acid groups. With their low formal potentials, they have found most use in acidic conditions with strong reducing agents such as tin(II), titanium(III), and chromium(II). The most widely used is indigo-5,5'-disulfonic acid under the name indigo carmine ((11) and (12)).

### Indophenols

These are two-electron redox indicators with  $E'_0$  at 0.54–0.69 V. Quoted  $E'_0$  values are generally extrapolations, as these compounds decompose in strong acid. They are especially useful in alkaline solution.

### Azo Dyes

Many diazo dyes have been examined as redox indicators. Although distinct color changes are observed for many on oxidation, the changes are nonreversible, and, in general, these compounds have no advantages over other classes of reversible indicators.

### Azines, Oxazines, and Thiazines

These are two-electron redox indicators based on phenazine, phenoxazine, or phenthiazine (13) structures. Their  $E'_0$  values range from 0.05 to 0.58 V. This means that they are principally used in the presence of such strong reducing agents as titanium(III), chromium(II), or vanadium(II). Typical examples of these compounds, which have been used as redox

indicators, are brilliant cresyl blue, methylene blue, and brilliant alizarin blue ((14)–(16)).

Phenazine X = Y = NH  
 Phenoxazine X = O, Y = NH  
 Phenothiazine X = S, Y = NH

Brilliant cresyl blue

(14)

Methylene blue

(15)

Brilliant alizarin blue

(16)

### Indamines and Indoanilines

These compounds have been used as redox indicators, but have a limited range of pH stability. The indoaniline phenol blue (17) has an  $E'_0$  value of 0.68 V, but decomposes in both acidic and alkaline solution, and so can only be used safely in solutions of pH 3–9. The related indamine, Bindschedler's green (18), with an  $E'_0$  of 0.68 V can be used over a pH range wider than phenol blue and related compounds, but decomposes in strong acid or alkali.

Phenol blue

### Chemiluminescent Redox Indicators

Chemiluminescent reactions usually involve oxidation of an organic molecule. The chemiluminescent oxidation of luminol (19) is well known.

Luminol

(19)

This chemiluminescence can be used to detect the presence of excess oxidant after a reductant has been oxidized. Chemiluminescent light levels are low, and darkened ambient conditions are needed to detect the chemiluminescence.

### Fluorescent Redox Indicators

These are used in a similar way to visual indicators but, instead of color change being detected, one form of the indicator is fluorescent, and its presence can be detected by a suitable fluoroscope. Useful fluorescent indicators are the ruthenium analogs of ferroin, and tris(2,2'-bipyridyl)iron. In these, the reduced ruthenium(II) complexes show an orange-red fluorescence that disappears on oxidation to ruthenium(III).

## Complexometric, Adsorption, and Luminescence Indicators

**K Krishnankutty**, University of Calicut, Malappuram, Kerala, India

### Introduction

Although numerous highly efficient instrumental methods are now available for the determination of metal ions and other inorganic species, complexometric titrations are still widely used in routine analysis. The versatility, sensitivity, and general convenience of complexometric titrations are dependent on the correct choice of indicators for endpoint detection. The endpoint detection in complexometric titration was revolutionized by Schwarzenbach in the 1940s with the discovery of visual color indicators sensitive to the concentration of metal ions in solution. A wide variety of such indicators, often called complexometric or metal ion indicators, are available for the selective determination of almost all metal and metalloid ions from a variety of matrices. In this article, the basic mode of action of these visual indicators, their classification, and relevant details on the use of typical indicators are discussed.

Compared to complexometric indicators, the use of adsorption and luminescence indicators is limited. However, they are important in many specified areas of chemical analysis. The essential theory of action of these two types of indicator systems in titrimetric analysis and important examples of practical value are also included in this article.

### Complexometric Indicators

Visual methods that can be used to indicate the endpoint in complexometric titrations almost always involve complex formation between the indicator and the metal ion whose pM ( $-\log_{10}[\text{metal ion}]$ ) changes sharply at the endpoint. In complexometric titrations in which a complexing agent (e.g., EDTA) is added to a solution of a metal ion, the pM changes slowly until at the equivalence point, when virtually all the metal ions are complexed, a sudden and rapid increase in pM occurs. Metal indicators detect the disappearance of the last traces of free metal ion by forming a colored complex with the metal ion, and showing a different color or no color at all when all the particular metal ions have been complexed by the titrant. That is, the color of the metal-indicator complex and the free indicator should differ significantly.

Numerous compounds are known to form colored products with metal ions, but only a few of these are

suitable as visual indicators. The essential requirements of such metal indicators can be summarized as follows: (1) The color must be sufficiently intense that a minimal amount of the indicator is needed. (2) The color contrast between the free indicator and the metal-indicator complex must be sufficient to permit easy visual observation. (3) The metal-indicator complex must be weaker than the metal-titrant complex. (4) The formation of the metal-indicator complex and its reaction with the titrant must be sufficiently rapid and preferably reversible in order to ensure an abrupt color change at the equivalence point. (5) The metal-indicator complex must have an appropriate stability; extended dissociation will cause the color change interval to be spread over several drops of titrant. (6) To ensure a sharp endpoint, the metal-to-indicator ratio in the complex should preferably be 1:1. (7) The color reaction between the metal and the indicator should be selective, with as little interference as possible from other metal ions. (8) The indicator must be stable in the titration medium.

### Mode of Action

Organic compounds, usually dyestuffs, with acid-base properties and sensitive to low concentrations of metal ions, are the most important complexometric indicators (also termed metallochromic indicators). In most cases the indicator and the metal-indicator complex are both colored, so that the endpoint of the titration is characterized by a change in color. Like most complexing titrants, these indicators are also capable of forming chelate rings with the metal ion. They are also usually polybasic acids that change color with the pH of the solution. Suitable buffer mixtures are then necessary during the titration. For indicators of high molar absorptivity ( $10^4$ – $10^5 \text{ mol}^{-1} \text{ l cm}^{-1}$ ), indicator concentrations of  $10^{-6}$ – $10^{-5} \text{ mol l}^{-1}$  are sufficient to give a clearly detectable color change, and therefore the indicator error is generally negligible. On the other hand, there are colorless or weakly colored indicators that form colored metal-indicator complexes. Because of the relatively low molar absorptivities ( $\sim 10^3 \text{ mol}^{-1} \text{ l cm}^{-1}$ ) of these complexes, indicator concentrations of  $10^{-5}$ – $10^{-4} \text{ mol l}^{-1}$  are necessary to produce a detectable color.

The use of a metal (M) indicator in complexometry may be represented in the following reactions:

The indicator  $H_nI$  and the titrant  $H_nY$  are considered to be in fully dissociated anionic forms  $I$  and  $Y$  (charges are omitted for convenience). The reaction will proceed if the metal-indicator complex  $MI$  is sufficiently less stable than the metal-titrant complex  $MY$ . Here it is assumed that the indicator acid forms only a 1:1 metal complex  $MI$ , and that it is not involved in any side reaction. The stability constant  $K_{MI}$  is

$$K_{MI} = \left( \frac{[MI]}{[M][I]} \right) \quad [1]$$

$MI$  and  $I$  should have different colors. The color change will occur when  $[MI] \approx [I]$ . The transition point is expressed as  $pM_{trans}$  from eqn [1]:

$$pM_{trans} = -\log[M_{trans}] = \log K_{MI} \quad [2]$$

$pM_{trans}$  is a measure of the sensitivity of the indicator, a large value indicating high sensitivity.

The above reactions were obtained by ignoring all the possible side reactions between the indicator and various species present in the medium. In acidic solution the indicator usually occurs as one or more protonated forms  $HI$ ,  $H_2I$ , ...,  $H_nI$ , and only a very small fraction exists as the ion  $I$ . Thus, instead of  $[I]$  in eqn [1], it may be more appropriate to use  $[I']$ , where

$$[I'] = [I] + [HI] + \dots + [H_nI] \quad [3]$$

and the color change occurs when  $[MI] = [I']$ . The relationship between  $[I]$  and  $[I']$  is denoted by the coefficient  $\alpha$ :

$$\alpha_{HI} = \frac{[I']}{[I]} \quad [4]$$

By combining eqns [1] and [4],

$$\frac{[MI]}{[M][I']} = \frac{K_{MI}}{\alpha_{HI}} = K_{MI'} \quad [5]$$

$K_{MI'}$  is the apparent, conditional, or effective stability constant. It is not a real constant since it depends on experimental conditions (here pH). From eqn [5],

$$pM_{trans} = \log K_{MI} - \log \alpha_{HI} = \log K_{MI'} \quad [6]$$

The effect of side reactions of the metal ion on the color change can similarly be estimated by introducing  $[M']$  and  $\alpha_M$ . The corresponding expressions are

$$K_{M'I'} = \frac{[MI]}{[M'][I']} = \frac{K_{MI}}{\alpha_M \alpha_1} \quad [7]$$

$$pM'_{trans} = \log K_{M'I'} + \log \left( \frac{[I']}{[MI]} \right) \quad [8]$$

Since  $[I'] = [MI]$ , at the transition point

$$pM'_{trans} = \log K_{M'I'} \quad [9]$$

Therefore, the sensitivity of a metal indicator expressed as  $pM'_{trans}$  is equal to the logarithm of the conditional stability constant of the metal-indicator complex. Although the formation of  $MI_2$ ,  $MI_3$ , ...,  $MHI$ ,  $MOHI$ , ...,  $M_2I$  or  $M_nI$  type species can also influence the color change of an indicator, their effect is seldom very great. An indicator error may arise owing to the residual binding of some of the metal ions to the indicator at the endpoint. For accurate results, a correction has to be applied.

As the values of the dissociation constants of a large number of indicators are known, the  $pM$  values at which a color change occurs at various pH values, and the values of  $pM'_{trans}$  ( $= pM_{trans} - \log \alpha_M$ ) can be determined. The  $\alpha_M$  values depend on the nature and concentrations of buffer, masking agents, etc. present in the medium. In this way, it is possible to compare the sensitivities of the various indicators under various experimental conditions and to choose the most suitable indicator for a particular titration. There are certain factors that are detrimental to the effective functioning of an otherwise good indicator, such as impurities present in the indicator and the presence of other, strongly binding metal ions that can block the color change.

### Classification of Metallochromic Indicators

In general, these compounds contain at least two auxochromic groups bound to the conjugated chromophoric system. In addition, metal-binding groups such as  $OH$ ,  $NH_2$ ,  $COOH$ , etc., at suitable positions are also necessary to form stable five- or six-membered chelate rings with the metal ion. The number of substances tried and recommended as metallochromic indicators is large and even a specialist has difficulty in proper selection. Many of the recently reported indicators are of no great practical value. Therefore, in Table 1, only selected typical and readily available indicators are given. The indicators can be classified according to their structural types as (a) diarylazo dyes including compounds containing heterocyclic rings (1–26 in Table 1), (b) triphenylmethane derivatives (27–37 in Table 1), (c) anthracene derivatives (38–40 in Table 1), and (d) miscellaneous structural types.

From an analytical point of view, the following information is provided in the table. (1) The trivial name rather than the polysyllabic systematic nomenclature (chemical reagent manufacturers' catalogs contain trivial names also). As many of the compounds are commercial dyestuffs, a single dye may be

described by different trade names, so at least one such synonym, if available, is also given together with the color index number, if any. (2) The metal ions that can be titrated, the pH and buffer medium, and the color change at the equivalence point.

## Adsorption Indicators

Adsorption indicators were first introduced by Fajans for the detection of endpoints of precipitation titrations, particularly in argentimetry. Any substance that forms a deformable anion or cation exhibiting different colors in solution and when adsorbed may be capable of functioning as an adsorption indicator in a precipitation titration. Since any large ion is

deformable and all ionic precipitates show strong adsorptive properties, the field is extensive. In practice, colloidal precipitates that have a large surface-to-mass ratio, and organic dyestuffs that are weak acids or bases provide a fruitful field for the application of this technique. The classic example involves lyophobic silver halides and the anionic fluorescein family of dyes.

**Theory.** The action of these indicators is based on the properties of colloids and can readily be explained by considering the determination of chloride using silver nitrate solution as a titrant in the presence of fluorescein as indicator. The adsorption characteristics of AgCl precipitated during titration are shown diagrammatically in **Figure 1**.

At the equivalence point,  $\text{Ag}^+$  ions begin to be present in excess and the adsorbed layer corresponds to (B). However, the negatively charged fluorescein,  $\text{I}^-$ , when present in the solution, is adsorbed more strongly than  $\text{NO}_3^-$  and the precipitate appears pink. The color is due to the formation of a complex of silver and a distorted fluorescein ion on the surface at the appearance of the first trace of excess  $\text{Ag}^+$  ion. The origin of the color change is also attributed to a rearrangement of the structure of the indicator ion during the adsorption process. Thus, the indicator ion must be of opposite charge to the precipitating ion, and the indicator should only be adsorbed strongly immediately after the equivalence point. Typical adsorption indicators and their applications are listed in **Table 2**. The indicators have also been classified into surface precipitation, surface acid-base, surface redox, surface complexometric, and surface fluorescent indicators based on their mode of action.

## Luminescent Indicators

Depending on the source of energy producing excited-state molecules, luminescent indicators available for titrimetric analysis can be conveniently divided into fluorescent (F) and chemiluminescent (CL) indicators. In the former incident radiation produces the excited state, and in the latter the chemical energy of a reaction raises a molecule or one of the reaction products to its excited state. The two types are considered separately below.

## Fluorescent Indicators

**Theory.** The F properties (such as color, intensity, or quenching of fluorescence) of many substances in solution are strongly dependent on the nature and concentration of other ions present in solution. The substances whose F characteristics are sensitive to pH (acid-base), pM (metallochromic), oxidation potential (redox), and adsorption effects (adsorption) have been used as indicators in appropriate titrimetric analyses.

The fluorescence of a good acid-base indicator should be in the visible region, and either the indicator  $\text{H}_n\text{I}$  or its ionized form  $\text{I}^-$  (charges are omitted) may be the fluorophore (see reaction [III]).

More than 75 F compounds have been recommended as acid-base indicators. These compounds conform to a few structural types. Typical compounds are listed in **Table 3A** along with their color change at the equivalence point, the pH range, and other relevant information.

In the case of F redox indicators, the oxidized state or the reduced state of the molecule is either F or non-fluorescent. Very few compounds have been proposed as F indicators for redox titrations. Rhodamine B and fluorescein are noted for the determination of  $\text{Sn(II)}$  and  $\text{As(III)}$  using  $\text{IO}_3^-$ ,  $\text{BrO}_3^-$ , and  $\text{MnO}_4^-$ .

**Table 2** Typical adsorption indicators

No.	Indicator	Ions titrable <sup>a</sup>	Color change at endpoint <sup>b</sup>
1	Alizarin sulfonic acid (Alizarin red)	$\text{SCN}^-$ , $\text{Fe(CN)}_6^{4-}$ , $\text{MoO}_4^{2-}$	Y/R
2	Bromophenol blue	$\text{Cl}^-$ , $\text{I}^-$	Y-G/B
3	Dichloro(P)fluorescein	$\text{Cl}^-$ , $\text{Br}^-$ , $\text{I}^-$	Y-G/Pk
4	Dichloro(P)tetraiodo(R)fluorescein (rose bengal)	$\text{I}^-$ in presence of $\text{Cl}^-$	R/B-R
5	Dichloro(R)fluorescein	$\text{Cl}^-$ , $\text{Br}^-$ , $\text{I}^-$ , $\text{BO}_3^-$	Y-G/R
6	Diiodo(R)fluorescein (erythrosin)	$\text{I}^-$	Y-R/R-V
7	Dimethyl(R)fluorescein	$\text{Cl}^-$ , $\text{Br}^-$ , $\text{I}^-$	G-Y/Pk
8	Diphenylamine	$\text{Cl}^-$ , $\text{Br}^-$ , $\text{I}^-$ , $\text{SCN}^-$	V/G
9	Fluorescein (resorcinol phthalein)	$\text{Cl}^-$ , $\text{Br}^-$ , $\text{I}^-$ , $\text{SCN}^-$	Y-G/Pk
10	Fluorescein complexone	$\text{Br}^-$ , $\text{I}^-$ , $\text{SCN}^-$	Y/Pk
11	Methyl red	$\text{Zn}^{2+}$ , $\text{Fe(CN)}_6^{4-}$	Pk/Y
12	Phenosafranine	$\text{Cl}^-$ , $\text{Br}^-$ , $\text{Ag}^+$ ( $\text{Br}^-$ )	R/B
13	Tartrazine	$\text{I}^- + \text{Cl}^-$ ; $\text{Ag}^+$ ( $\text{Cl}^-$ , $\text{Br}^-$ , $\text{I}^-$ , $\text{SCN}^-$ )	C/G
14	Tetrabromo(R)fluorescein (eosin)	$\text{Br}^-$ , $\text{I}^-$ , $\text{SCN}^-$	Pk/R-V
15	Tetrachloro(P)tetrabromo(R)fluorescein (phloxin)	$\text{Br}^-$ , $\text{I}^-$	Y-R/R-V
16	Tetraiodo(R)fluorescein (erythrosin-B)	$\text{I}^-$	R/B-R

<sup>a</sup>Titrimetric other than  $\text{Ag}^+$  are in parentheses.

<sup>b</sup>Abbreviations are as in **Table 1**.

as titrants. In cerimetry, Rhodamine 6G in the determination of U(IV), Fe(III), and V(IV) and 2,2'-bipyridyl for Ru(II) are some of the F redox indicators.

The function of metallofluorescent indicators is similar to metal-ion indicators in the sense that the endpoint of the titration is indicated by a change in F characteristics due to the destruction or formation of the metal-indicator complex. Although there are several organic compounds whose F characteristics are influenced by metal ions under specified conditions, only a

limited number have real use as indicators. A list of such indicators is given in Table 3B. Many of these compounds have fluorescent as well as chelating properties.

### Chemiluminescent Indicators

Although numerous CL reactions are known, relatively very few systems have proved useful as indicators in titrimetry. These are based largely on the CL reactions of luminol, lucigenin, lophine, and

Siloxene	Ce(IV)	Fe <sup>2+</sup>
	Cr <sub>2</sub> O <sub>7</sub> <sup>2-</sup>	Fe <sup>2+</sup> , Ti <sup>+</sup> , hydroquinone

siloxene systems. Their use as CL indicators is based on the fact that light emission is initiated only under definite conditions of pH and redox potential. If the conditions for the start or termination of the CL reaction are those obtained at the endpoint of a titration, the indicator will function properly to yield or quench chemiluminescence. The CL reaction of these systems is oxidative, involving oxygen, peroxide, or another strong oxidizing agent. CL indicators do not require an excitation light source or other special equipment, unlike F indicators. The CL emission can easily be observed in a semi-darkened room.

The indicator systems recommended for acid–base titrations are listed in Table 4A. The pH range and color of the CL emission and the indicator preparation are also included. In a typical direct titration, the indicator, an oxidant (usually 3% H<sub>2</sub>O<sub>2</sub> solution), and a catalyst (such as Fe(CN)<sub>6</sub><sup>3-</sup> or blood hemin in the case of luminol and lophine) are added to the acid

and titrated against the base. The equivalence point is indicated by the initiation of bright CL emission. These indicators were successfully used for the determination of the acidity of intensely colored and turbid solutions such as milk, wines, fruit juices and mustard, and the saponification number of fats and oils. Since H<sub>2</sub>O<sub>2</sub> is essential for the CL reaction, the indicator cannot be used in the presence of heavy metals, as H<sub>2</sub>O<sub>2</sub> is decomposed before the endpoint. Further, in most cases the indicator is irreversible.

In alkaline solutions when suitable reducing agents are titrated with oxidizing agents such as H<sub>2</sub>O<sub>2</sub> or a hypohalite in the presence of luminol and lucigenin, at the endpoint the redox potential of the solution suddenly moves towards a more positive value and the CL reaction occurs. In acidic solution (pH < 3.5), siloxene has been used as a CL redox indicator. An outline of the use of these indicators in redox titrations is presented in Table 4B.

### Introduction

The infrared (IR) region of the electromagnetic spectrum lies between  $\sim 10$  and  $12\,800\text{ cm}^{-1}$ . The

energy of IR photons is thus of the same order of magnitude as the energy differences between quantized molecular vibrational states. Transitions between these vibrational modes can be induced by IR radiation if there is a change in the molecular electric dipole moment in the course of the vibrational motion. IR spectroscopy is the study of the interaction of IR radiation with matter as a function of photon frequency. This interaction can take the form of absorption, emission, or reflection. IR spectroscopy is a fundamental analytical technique for obtaining quantitative and qualitative information about a substance in the solid, liquid, or vapor state.

### Introduction

The infrared (IR) region of the electromagnetic spectrum lies between  $\sim 10$  and  $12\,800\text{ cm}^{-1}$ . The

energy of IR photons is thus of the same order of magnitude as the energy differences between quantized molecular vibrational states. Transitions between these vibrational modes can be induced by IR radiation if there is a change in the molecular electric dipole moment in the course of the vibrational motion. IR spectroscopy is the study of the interaction of IR radiation with matter as a function of photon frequency. This interaction can take the form of absorption, emission, or reflection. IR spectroscopy is a fundamental analytical technique for obtaining quantitative and qualitative information about a substance in the solid, liquid, or vapor state.

**Table 1** The IR region of the spectrum

Region	$\lambda$ (cm)	$\bar{\nu}$ ( $\text{cm}^{-1}$ )	$\nu$ (Hz)
Near-IR	$2.5 \times 10^{-4}$ – $7.8 \times 10^{-5}$	4000–12 800	$1.2 \times 10^{14}$ – $3.8 \times 10^{14}$
Mid-IR	$5 \times 10^{-3}$ – $2.5 \times 10^{-4}$	200–4000	$6 \times 10^{12}$ – $1.2 \times 10^{14}$
Far-IR	$0.1$ – $5 \times 10^{-3}$	10–200	$3 \times 10^{11}$ – $6 \times 10^{12}$

It is convenient to divide the IR region into three parts (**Table 1**): the far-IR ( $10$ – $200 \text{ cm}^{-1}$ ); the mid-IR ( $200$ – $4000 \text{ cm}^{-1}$ ); and the near-IR ( $4000$ – $12\,800 \text{ cm}^{-1}$ ). (The regions are not exactly defined: slightly different boundaries for the IR regions are found in the literature. In particular, most Fourier transform infrared (FTIR) spectrometers operating in the mid-IR region have a low-wave-number limit of  $400 \text{ cm}^{-1}$ .) Each part of the spectrum plays a different role in analysis according to the different character of the transitions involved in each case.

Mid-IR radiation corresponds to fundamental transitions in which one vibrational mode is excited from its lowest energy state to its first excited state. For routine analysis a spectrum is normally taken from  $400$  to  $4000 \text{ cm}^{-1}$ . The mid-IR spectrum of a substance is effectively a unique fingerprint that can be used for the purpose of identification by comparison with a reference spectrum. When no reference spectrum is available, an IR spectrum can be used to identify the presence of certain structural units that, irrespective of their molecular environment, give rise to characteristic spectral features in a narrow frequency range.

Near-IR spectroscopy arises from transitions in which a photon excites a normal mode of vibration from the ground state to the second or higher excited vibrational state (overtones, *vide infra*) or transitions in which one photon simultaneously excites two or more vibrational modes (combinations bands, *vide infra*). The use of the near-IR, especially diffuse reflection spectroscopy, in both quantitative and qualitative analysis has increased significantly due to better instrumentation and the development of chemometrics to better handle the effect of seriously overlapping bands.

The far-IR region of the spectrum ( $<200 \text{ cm}^{-1}$ ) results from transitions involving low-frequency torsions and internal rotations in liquids and lattice vibrations in solids and is not commonly used for analysis, although recent developments in instrumentation for terahertz spectrometry may change the situation.

The scope and flexibility of IR spectroscopy in the mid-IR region have been greatly increased by the advent of FTIR spectroscopy. The multiplex and throughput advantages of this technique allow spectra to be run faster and with a greater signal-to-noise

ratio than dispersive spectroscopy, i.e., measurements made with prism or grating monochromators.

The following brief description of the principal IR techniques – using the near- or mid-IR – illustrates the range of sample handling possible with IR spectroscopy.

‘Diffuse reflection’ is the term used to describes the reflection of electromagnetic radiation from a sample after the radiation has undergone multiple scattering inside a powdered sample or at the surface of a matte substance. The radiation passes through the ‘micro-structural’ elements of the sample, e.g., the micro-crystallites of a powder or the surface fibers of a fabric, and is absorbed in the process before being scattered out of the sample to detector. The use of diffuse reflection spectroscopy in the ultraviolet (UV) region of the spectrum is a long-established technique. However, until FTIR was established, the weakness of the signal prevented the extension of the technique into the mid-IR. Diffuse reflection IR Fourier transform (DRIFT) spectroscopy has become a useful technique for obtaining IR spectra from powdered samples (or any matte material) with little or no sample preparation.

Photoacoustic IR spectroscopy has similar advantages to DRIFT spectroscopy in its ability to handle solids with the minimum of preparation. The principle of this technique is that when a modulated beam of IR radiation is absorbed by a sample, temperature oscillations set up thermal waves. If the sample is sealed in a cell and surrounded by gas, then a microphone can pick up the sound waves in the gas and an IR absorption spectrum generated.

‘Specular reflection’ is the term used to describe ‘mirror-like’ reflection, from the surface of a sample (angle of reflection equals angle of incidence). Specular reflected radiation ostensibly carries no information about the IR absorption of a sample and is a source of interference in diffuse reflection experiments when the sample is not completely matte, i.e., has an element of ‘shininess’ about it. However, if the reflected intensity from a sample is due ‘principally’ to reflection from the front surface of the sample, then an absorption index spectrum of the sample can be generated from the reflected intensity over the whole spectrum using the Kramers–Krönig transformation. (This complex transformation is an

integral part of the software packages driving most modern FTIR spectrometers.)

Aqueous solutions have traditionally posed a problem for IR spectroscopy due to the fact that water is a strong absorber of IR radiation. This difficulty, for aqueous solutions and other strongly absorbing liquid and solid samples, can be overcome by using attenuated total reflection spectroscopy. In this technique, the phenomenon of total internal reflection is used in such a way that it is only the evanescent wave associated with total internal reflection that enters the sample. The evanescent wave penetrates the sample very short distances only, hence the advantage for strongly absorbing species.

FTIR microscopy, in which IR spectra can be obtained from picogram quantities, is an invaluable nondestructive analytical tool in fields such as forensic science and pharmaceutical analysis.

The short data-capture times possible with the FTIR spectrometer means that time-resolved spectroscopy has become an important means of following the course of a chemical reaction in order to obtain information about kinetics, equilibria, and the nature of reaction intermediates.

Matrix isolation IR spectroscopy involves mixing trace amounts of solute into a rare gas matrix at low temperature. The advantage is that the solute molecules are isolated so that reactive species can be analyzed. Also, the absence of rotational structure and lattice modes increases resolution.

For chiral molecules a small difference in the magnitude of absorption of left- and right-circularly polarized IR radiation is observed. This is known as vibrational circular dichroism and, since the effect can be observed from each normal mode, absolute stereochemical information can be obtained from the entire molecule. This is different from the UV analog of this effect, where there may often be only one chromophore present.

## The Vibration of Diatomic Molecules

### The Classical Diatomic Rigid Vibrator

An understanding of the nature of vibrational motion is best obtained by first studying a simple system. To introduce some of the basic concepts involved it is useful to study the classical diatomic vibrator before going on to consider the quantum theory.

The simplest model for a diatomic molecule consists of two atoms of mass  $m_1$  and  $m_2$  connected by a rigid, massless spring of length  $r$ , which has the value  $r_0$  at equilibrium (Figure 1). If the  $z$ -axis is taken to lie along the internuclear line, then the Cartesian coordinates of the two atoms, referred to the center of

Figure 1 Model for a rigid diatomic vibrator.

mass, may be written as

$$z_1 = z_1^0 + \Delta z_1 \quad [1a]$$

$$z_2 = z_2^0 + \Delta z_2 \quad [1b]$$

where  $z_1^0$  and  $z_2^0$  are the equilibrium coordinates of atoms 1 and 2, respectively, and  $\Delta z_1$  and  $\Delta z_2$  are the 'Cartesian displacements coordinates'. An 'internal coordinate'  $R$  can be defined as the differences in the bond length from its equilibrium value

$$R = \Delta z_2 - \Delta z_1 = r - r_0 \quad [2]$$

The potential energy of the molecule  $V(R)$ , which increases as the bond is stretched or compressed, may be expressed as a power series in the internal coordinate

$$V(R) = V(0) + \left( \frac{dV(R)}{dR} \right)_0 R + \frac{1}{2} \left( \frac{d^2 V(R)}{dR^2} \right)_0 R^2 + \frac{1}{6} \left( \frac{d^3 V(R)}{dR^3} \right)_0 R^3 + \cdots \quad [3]$$

The subscripts (zero) indicate that the derivatives are to be taken at the equilibrium bond length. Only changes in the potential energy from the equilibrium value are important, so the energy scale may be chosen such that  $V(0)$  is zero. Also, the first derivative of the potential energy  $(dV(R)/dR)_0$  must be zero by definition at the equilibrium position since this corresponds to the energy minimum. This leaves only the quadratic and higher terms in the potential function

$$V(R) = \frac{1}{2} \left( \frac{d^2 V(R)}{dR^2} \right)_0 R^2 + \frac{1}{6} \left( \frac{d^3 V(R)}{dR^3} \right)_0 R^3 + \cdots \quad [4]$$

The cubic and higher terms are generally small for small departures from the equilibrium position. The effects of including these contributions in the potential energy expression will be considered later. It is, however, a good first approximation to set these higher-order terms to zero to give

$$V(R) = \frac{1}{2} \left( \frac{d^2 V(R)}{dR^2} \right)_0 R^2 = \frac{1}{2} K R^2 \quad [5]$$

A system with a potential function given by eqn [5] is said to be 'mechanically harmonic' and  $K$  is known

as the ‘force constant’ for the bond where

$$K = \left( \frac{d^2 V(R)}{dR^2} \right)_0 \quad [6]$$

The harmonic approximation corresponds to a restoring force  $F$  acting on the atoms that is proportional to the displacement of the bond length from its equilibrium value (Hooke’s law)

$$F = -KR \quad [7]$$

With the center of gravity as the coordinate origin, it is straightforward to show that the problem reduces to that of a single particle oscillating around the center of mass subject to a harmonic restoring force whose displacement is equal to the change in the internuclear distance of the molecule, i.e., the internal coordinate  $R$ . The mass  $\mu$  of this particle is known as the reduced mass of the molecule and is given by

$$\mu = \frac{m_1 m_2}{m_1 + m_2} \quad [8]$$

Applying Newton’s second law gives

$$\frac{\mu}{2} \frac{d^2 R}{dt^2} = -KR \quad [9]$$

This equation describes the simple harmonic oscillator. The solution is

$$R = R^0 \sin(2\pi\nu t + \delta) \quad [10]$$

which corresponds to simple harmonic motion with maximum amplitude  $R^0$ , phase factor  $\delta$ , and frequency  $\nu$  given by

$$\nu = \frac{1}{2\pi} \left( \frac{K}{\mu} \right)^{1/2} \quad [11]$$

It can be shown that the maximum amplitude of vibration for each atom is inversely proportional to the atomic mass.

### The Quantum-Mechanical Harmonic Diatomic Vibrator

The harmonic potential function obtained in eqn [5]

$$V(R) = \frac{1}{2} KR^2$$

can be used in Schrödinger’s equation to yield the following wave function:

$$\Psi_v(R) = \frac{(\alpha/\pi)^{1/4}}{(2^v v!)^{1/2}} \exp\left(-\frac{\alpha R^2}{2}\right) H_v(\alpha^{1/2} R) \quad [12]$$

where  $\nu$  is the vibrational quantum number, and

$$\alpha = 2\pi \frac{(\mu K)^{1/2}}{h} = \frac{4\pi^2 \mu \nu}{h}$$

where  $H_v(\alpha^{1/2} R)$  are Hermite polynomials (Table 2).

**Table 2** The first few Hermite polynomials

$\nu$	$H_\nu(x)$
0	1
1	$2x$
2	$4x^2 - 2$
3	$8x^3 - 12x$
4	$16x^4 - 48x^2 + 12$
5	$32x^5 - 160x^3 + 120x$

The vibrational energy levels are given by

$$E_\nu = \left(\nu + \frac{1}{2}\right) h\nu, \quad \nu = 0, 1, 2, \dots \quad [13]$$

where

$$\nu = \frac{1}{2\pi} \left( \frac{K}{\mu} \right)^{1/2}$$

Note that this expression is exactly the same as eqn [11], the classical vibration frequency.

Vibrational term values  $G(\nu)$  in wave numbers can be defined from eqn [13]:

$$G(\nu) = \frac{E_\nu}{hc} = \left(\nu + \frac{1}{2}\right) \frac{h\nu}{c} = \left(\nu + \frac{1}{2}\right) \tilde{\nu} \quad [14]$$

Inspection of eqn [13] shows that the vibrational zero-point energy  $E_0$  is given by

$$E_0 = \frac{1}{2} h\nu \quad [15]$$

or

$$G(0) = \frac{1}{2} \tilde{\nu} \quad [16]$$

Figure 2 shows plots of the harmonic diatomic vibrator wave functions.

For harmonic wave function, the properties of the Hermite polynomials are such that the selection rules for vibrational transitions are

$$\Delta\nu = \pm 1 \quad [17]$$

There also exists the gross selection rule that, in order for electromagnetic radiation to be absorbed, the dipole moment of the molecule must change during the vibration, which means that a diatomic molecule must possess a permanent dipole moment in order to absorb IR radiation. (These selection rules will be discussed in detail in the section on the intensity of IR transitions.)

Since all energy levels are equally spaced for a harmonic diatomic vibrator, one line will appear in the IR absorption spectrum with wave number

$$\tilde{\nu} = \frac{1}{2\pi c} \left( \frac{K}{\mu} \right)^{1/2} \quad [18]$$

**Figure 2** Harmonic diatomic vibrator wave functions.

Equation [18] can be used to provide approximate values for the force constants of bonds (Table 3).

### Isotopic Substitution

If one of the atoms in the diatomic molecule is replaced by another isotopic species, then to a good approximation the electronic structure is unchanged. Hence, the force constant will be the same for both molecules. The change in the vibrational frequency will therefore be completely due to the change in the reduced mass. If  $\mu'$  and  $\tilde{\nu}'$  are the reduced mass and wave number of the isotopically substituted molecule, then

$$\frac{\tilde{\nu}'}{\tilde{\nu}} = \left(\frac{\mu'}{\mu}\right)^{1/2} \quad [19]$$

Similar relationships for frequency shifts induced by isotopic substitution in polyatomic molecules are given later.

**Figure 3** The Morse potential function.

### Anharmonic Vibrations of a Diatomic Molecule

The true potential function for a diatomic molecule departs from harmonicity, especially for large amplitude vibrations. It is useful to approximate an anharmonic potential using a Morse function (Figure 3)

$$E_{\text{anh}} = D_e \{1 - \exp[-a(r - r_e)]\}^2 \quad [20]$$

where  $D_e$  is the thermodynamic dissociation energy and

$$a = \omega \left(\frac{\mu}{2D_e}\right)^{1/2}, \quad \omega = 2\pi\nu \quad [21]$$

When this potential energy is used in the Schrödinger equation the vibrational levels become

$$G(\nu) = \left(\nu + \frac{1}{2}\right) \tilde{\nu}_e - \left(\nu + \frac{1}{2}\right)^2 x_e \tilde{\nu}_e, \dots, \quad x_e = \frac{a^2 \hbar}{2\mu\omega} \quad [22]$$

where  $\tilde{\nu}_e$  is the wave number corrected for anharmonicity, and  $x_e$  is the anharmonicity constant, a positive number  $\sim 10^{-2}$ . The negative term in eqn [22] results in the gap between successive vibrational energy levels decreasing as  $\nu$  increases. The point at which the levels merge into a continuum corresponds to the dissociation of the molecule.

Another effect of anharmonicity is to relax the selection rules to give

$$\Delta\nu = \pm 1, \pm 2, \pm 3, \dots \quad [23]$$

Along with the fundamental vibrations, 'harmonics' are now observed in the IR spectrum: the second harmonic (or first overtone) ( $\nu = 2 \leftarrow \nu = 0$ ), third harmonic (or second overtone) ( $\nu = 3 \leftarrow \nu = 0$ ) and so on occur with decreasing intensity. A knowledge of the wave numbers of the fundamental and first

**Table 4** Anharmonicity constants for some diatomic molecules

Bond	$\bar{\nu}_e$ ( $\text{cm}^{-1}$ )	$x_e \bar{\nu}_e$ ( $\text{cm}^{-1}$ )
H- <sup>12</sup> C	2861.6	64.3
H- <sup>19</sup> F	4138.5	90.07

H-Br	2649.7	45.21

overtone vibrations allows the anharmonicity constants to be calculated using eqn [22]. Table 4 shows values of anharmonicity constants for a selection of diatomic molecules.

## Normal Coordinates

Computational and interpretational aspects of vibrational spectroscopy are greatly simplified by the introduction of ‘normal coordinates’. First, mass-weighted Cartesian displacement coordinates for an  $N$ -atom molecule  $q_1, q_2, \dots, q_{3N}$  are defined according to

$$\begin{aligned} q_1 &= \sqrt{m_1} \Delta x_1, & q_2 &= \sqrt{m_1} \Delta y_1, \\ q_3 &= \sqrt{m_1} \Delta z_1, & q_4 &= \sqrt{m_2} \Delta x_2, \dots \end{aligned} \quad [24]$$

In these coordinates the kinetic energy  $T$  is given by

$$T = \frac{1}{2} \sum_{i=1}^{3N} \dot{q}_i^2 \quad [25]$$

where the dot indicates a time derivative. The potential energy is given by

$$\begin{aligned} V &= \frac{1}{2} \sum_{i,j=1}^{3N} \left( \frac{\partial V}{\partial q_i \partial q_j} \right)_0 q_i q_j \\ &= \frac{1}{2} \sum_{i,j=1}^{3N} b_{ij} q_i q_j \end{aligned} \quad [26]$$

where the  $b_{ij}$  denote the force constants in the Cartesian displacement coordinate system. (Note that there are cross-terms in the potential function involving two coordinates.)

The total energy is therefore given by

$$E = \frac{1}{2} \sum_{i=1}^{3N} \dot{q}_i^2 + \frac{1}{2} \sum_{i,j=1}^{3N} b_{ij} q_i q_j \quad [27]$$

If the potential energy term did not include any cross-terms, then Newton’s equation could be applied

$$\frac{d}{dt} \left( \frac{\partial T}{\partial \dot{q}_i} \right) + \left( \frac{\partial V}{\partial q_i} \right) = 0, \quad i = 1, 2, \dots, 3N \quad [28]$$

In this case the problem would reduce to the solution of  $3N$  independent equations. Therefore, in order to

enable the use of Newton’s equation, the mass-weighted Cartesian coordinates  $q_i$  are transformed into a set of new coordinates  $Q_i$  which results in no cross-terms in the potential function.

The  $Q_i$  are called the ‘normal coordinates’ of the system, and this transformation from Cartesian displacement to normal coordinates is the essence of the vibrational problem. Using normal coordinates, the kinetic and potential energy become

$$T = \frac{1}{2} \sum_{i=1}^{3N} \dot{Q}_i^2 \quad [29]$$

$$V = \frac{1}{2} \sum_{i=1}^{3N} \lambda_i Q_i^2 \quad [30]$$

Using eqns [29] and [30] in eqn [28] instead of the mass-weighted Cartesian coordinates gives

$$\ddot{Q}_i + \lambda_i Q_i = 0, \quad i = 1, 2, \dots, 3N \quad [31]$$

These are simply harmonic oscillator equations with solutions

$$Q_i = Q_i^0 \sin(\sqrt{\lambda_i} t + \delta_i) \quad [32]$$

with frequencies

$$\nu_i = \frac{1}{2\pi} \sqrt{\lambda_i} \quad [33]$$

Each vibration associated with a normal coordinate is known as a ‘normal vibration’. Each atom involved in a normal coordinate vibrates in phase with all the other atoms involved in the same vibration. Each atom passes through its equilibrium position at the same time and reaches each turning point at the same time.

An analysis of the stretching vibrational motion of a symmetrical linear triatomic molecule (Figure 4) reveals that in terms of mass-weighted Cartesian coordinates  $q_1, q_2$ , and  $q_3$  the normal vibrations (excluding a zero-frequency translational solution) are given by

$$Q_+ = \frac{1}{2^{1/2}} q_1 - \frac{1}{2^{1/2}} q_2 \quad [34a]$$

$$Q_- = \left[ \frac{M}{2(M+2m)} \right]_1^q - \left[ \frac{2m}{M+2m} \right]_2^q + \left[ \frac{M}{2(M+2m)} \right]_3^q \quad [34b]$$

with frequencies

$$\nu_+ = \frac{1}{2\pi} \left( \frac{K}{m} \right)^{1/2} \quad [35a]$$

$$\nu_- = \frac{1}{2\pi} \left[ \frac{K(M+2m)}{Mm} \right]^{1/2} \quad [35b]$$

**Figure 4** The symmetrical linear diatomic molecule.

The + and – labels have been used to denote that the two normal vibrations are symmetric and anti-symmetric stretches, respectively.

The two bonds in this system are known as ‘coupled oscillators’. This type of system occurs often in the vibrations of polyatomic molecules in which two oscillators (which can be bonds or groups of bonds) couple to give symmetric and antisymmetric combinations. (In this case, where the system is exactly symmetrical, the symmetric combination will not be observed in the IR spectrum because the dipole moment of the molecule does not change.)

## High-Resolution IR Spectra of Linear Molecules

Each vibrational transition of vapor-phase molecules is accompanied by rotational transitions. In the liquid state the effect of molecular collisions is to broaden the rotational lines so that they cannot be resolved. This is why one observes IR bands as opposed to lines in solution spectra. In the vapor phase, however, it is possible to resolve the rotational structure in a vibrational transition.

### The Diatomic Vibrating-Rotator

It is normally a good approximation to express the total energy due to the motion of the nuclei  $E_{\text{nuc}}$  as the sum of the separate energies  $E_{\text{vib}}$  and  $E_{\text{rot}}$  (the Born–Oppenheimer approximation)

$$E_{\text{nuc}} = E_{\text{vib}} + E_{\text{rot}} \quad [36]$$

To a first approximation, wave numbers of the rotational levels are given by

$$\frac{E_J}{hc} = BJ(J+1) \text{ cm}^{-1}, \quad J = 0, 1, 2, \dots \quad [37]$$

when  $J$  is the rotational quantum number and  $B$  is the rotational constant given by

$$B = \frac{h}{8\pi^2 Ic} \text{ cm}^{-1} \quad [38]$$

where  $I$  is the moment of inertia of the molecule given by

$$I = \mu r_e^2 \quad [39]$$

where  $r_e$  is the equilibrium bond length.

Using eqns [22] and [37] the total vibrational and rotational energy is given by

$$\frac{E_{v,J}}{hc} = BJ(J+1) + \left(v + \frac{1}{2}\right)\tilde{\nu}_e - x_e\left(v + \frac{1}{2}\right)\tilde{\nu}_e \quad [40]$$

The selection rules for vibration–rotation transitions are the same as for separate transitions:

$$\Delta v = \pm 1, \pm 2, \pm 3, \dots$$

and

$$\Delta J = \pm 1 \quad [41]$$

Labeling the initial and final levels by double and single primes, respectively, and making the assumption that the rotational constants for the lower and upper vibrational states are the same, then the transition energies are given by

$$\tilde{\nu}_{J',J''} = \tilde{\nu}_0 + B(J' - J'')(J' + J'' + 1) \quad [42]$$

when  $\nu_0$  is the band center (or band origin) given by

$$\tilde{\nu}_0 = \tilde{\nu}_e(1 - 2x_e) \quad [43a]$$

$$\tilde{\nu}_0 = 2\tilde{\nu}_e(1 - 3x_e) \quad [43b]$$

$$\tilde{\nu}_0 = 3\tilde{\nu}_e(1 - 4x_e) \quad [43c]$$

for the fundamental and first and second overtones, respectively. For  $\Delta J = +1$ ,

$$\tilde{\nu}_{J''+1,J''} = \tilde{\nu}_0 + 2B(J'' + 1), \quad J'' = 0, 1, 2, \dots \quad [44]$$

For  $\Delta J = -1$ ,

$$\tilde{\nu}_{J''-1,J''} = \tilde{\nu}_0 - 2B(J'' + 1), \quad J'' = 0, 1, 2, \dots \quad [45]$$

So it can be seen that the high-resolution spectrum will consist of two series of lines, one on either side of the band center. The series corresponding to  $\Delta J = -1$  is known as the P branch, and the series corresponding to  $\Delta J = +1$  is known as the R branch. Note that there is zero intensity at the line center. **Figure 5** shows a schematic diagram of the transitions involved and a stick representation of the line intensities which will be discussed below. **Figure 6** shows the high-resolution IR spectrum of the fundamental vibration of carbon monoxide and the same spectrum at lower resolution where only the envelope of the P and R branches can be seen.

**Figure 5** Schematic diagram of P and R branch transitions for a diatomic molecule, where the line thickness compounds to the intensity of the transition.

It has been assumed that the rotational constant  $B$  is the same for the upper and lower vibrational states and that the vibrational terms will be unaffected by the rotational state (interaction between rotation and vibration, i.e., a breakdown of the Born–Oppenheimer approximation). When these assumptions

are not made, eqn [40] becomes

$$\frac{E_{v,J}}{hc} = B_v J(J+1) + \left(\nu + \frac{1}{2}\right) \tilde{\nu}_e + x_e \left(\nu + \frac{1}{2}\right)^2 \tilde{\nu}_e - D_v J^2 (J+1)^2 + \dots \quad [46]$$

**Figure 6** The high-resolution infrared spectrum of carbon monoxide showing P and R branches. (Inset on right is the same band at lower resolution.)

where  $B_v$  is the rotational constant associated with the vibrational level with quantum number  $v$  and  $D_v$  is the centrifugal distortion coefficient associated with the vibrational level  $v$ . Centrifugal distortion arises due to the fact that a bond will lengthen hence weaken as the molecule rotates. The resultant vibrational-rotational energy change is therefore

$$\tilde{\nu}_{v'J',v''J''} = \tilde{\nu}_0 + B_{v'}J'(J'+1) - D_{v'}J'^2(J'+1)^2 - B_{v''}J''(J''+1) + D_{v''}J''^2(J''+1)^2 \quad [47]$$

### Intensity of Lines in the P and R Branches

The intensity of each rotational line depends on the number of molecules occupying the initial rotational state. Using the Boltzmann distribution formula, at thermal equilibrium the ratio of the number of molecules  $N_J$  in rotational state  $J$  to the number  $N_0$  in the rotational ground state is given by

$$\frac{N_J}{N_0} = (2J+1) \exp\left[-\frac{BhcJ(J+1)}{kT}\right] \quad [48]$$

where the  $(2J+1)$ -fold degeneracy of each rotational state has been taken into account. By differentiating eqn [48] with respect to  $J$  and setting the derivative to zero it can be shown that the maximum population and hence the maximum intensity line occurs at

$$J_{\max} = \left(\frac{kT}{2Bhc}\right)^{1/2} - \frac{1}{2} \quad [49]$$

This corresponds to a maximum intensity at wave number  $\tilde{\nu}_{\max}$  given by

$$\tilde{\nu}_{\max} = \tilde{\nu}_0 \pm 2B \left[ \left(\frac{kT}{2Bhc}\right)^{1/2} + \frac{1}{2} \right] \quad [50]$$

where the  $+$  and  $-$  signs refer to the R and P branches, respectively.

### High-Resolution Vibrational Spectra of Linear Polyatomic Molecules

The normal vibrations of a linear polyatomic molecule which result in a change in the molecular dipole

**Figure 7** Typical PQR branch envelope for the perpendicular vibration of a linear polyatomic molecule.

moment (i.e., are IR allowed) can be classified into two types: parallel vibrations and perpendicular vibrations, for which the directions of the changes in the molecular dipole moment are parallel and perpendicular to the internuclear axis, respectively. The rotational selection rules for parallel vibrations are the same as for the vibration of a diatomic molecule and one observes P and Q branches as before. However, for perpendicular vibrations, rotational transitions are allowed in which the rotational quantum number does not change, i.e.,

$$\Delta J = 0 \quad [51]$$

If rotational constants in both vibrational states are equal then all Q branch transitions occur at the same wavelength, the band origin. For a fundamental vibration of a perpendicular vibration with unequal rotational constants in the two vibrational levels and introducing centrifugal distortion

$$\tilde{\nu}_{v'J',v''J''} = \tilde{\nu}_0 + (B_{v'} - B_{v''})J^2 + (B_{v'} - B_{v''})J + (D_{v'} - D_{v''})J^2 + (D_{v'} - D_{v''})J, \quad J = 0, 1, 2, \dots \quad [52]$$

A typical band contour for perpendicular bands is shown in Figure 7.

## Polyatomic Molecules

### Internal Coordinates

The set of internal coordinates required to describe the vibrational motion of a general polyatomic molecule consists of the bond stretch  $r$ , the bond angle bend  $\phi$ , the out-of-plane (o.o.p.) angle bend  $\gamma$ , and the bond torsion  $\tau$  (Figure 8).

In a polyatomic molecule with  $3N-6$  vibrational degrees of freedom ( $3N-5$  for a linear molecule) a set

**Figure 8** Internal coordinates for polyatomic molecules.

**Figure 9** The normal vibrations of  $\text{H}_2\text{O}$ .

of  $3N-6$  internal coordinates can be chosen to describe the molecular vibrations.

A normal coordinate for a polyatomic molecule can be expressed as a linear combination of the internal coordinates. The vibrational behavior of the atoms can be represented by attaching arrows to show their direction of motion. The lengths of the arrows are in proportion to the maximum amplitudes of each atom's normal coordinate excursion. The normal vibrations of water ( $\text{H}_2\text{O}$ ) are shown in Figure 9.

**Characteristic or group frequencies** With a knowledge of atomic masses, the molecular geometry and force constants, it is possible to calculate the internal coordinate composition of the normal vibrations of any molecule. Without this mathematical help, it is not possible to specify the origin of most of the bands in an IR spectrum which will, in general, contain major contributions from several internal coordinates.

However, it is found that certain structural units in a molecule give rise to bands that appear in the

**Figure 10** Characteristic vibrations of the methylene group.

spectra of different molecules within a sufficiently narrow range of frequencies for these bands to be used to identify the presence of the structural unit. These relatively constant bands are known as the characteristic frequencies or group frequencies of a molecule. The vibrations associated with methylene and methyl groups, which give rise to important group frequencies, are shown in Figures 10 and 11, respectively.

### Intensity of IR Transitions

Let  $I_0$  and  $I$  be the incident and transmitted intensities, respectively, when infrared radiation passes through a sample of concentration  $C$  and cell length  $l$ . The transmittance  $T$  is defined as

$$T = \frac{I}{I_0} = 10^{-aCl} \quad [53]$$

where the quantity  $a$ , a function of wavelength, is called the absorptivity of the sample. Taking logarithms of the last equation, the absorbance of the sample is defined as

$$A = \log_{10} \left( \frac{I_0}{I} \right) = aCl \quad [54]$$

Equation [54] is known as the Beer-Lambert law: the absorbance of a sample is proportional to its concentration and the cell pathlength. Since  $A$  is a

**Figure 11** Characteristic vibrations of the methyl group.

dimensionless quantity, the units of  $a$  are the product of the units for reciprocal concentration and reciprocal pathlength. For example, with concentration in mol m<sup>-3</sup> and pathlength in meters, the units of  $a$  are m<sup>2</sup> mol<sup>-1</sup>. When concentration is expressed as molarity and the pathlength is either in meters or centimeters, the absorptivity  $a$  is known as the molar absorptivity and is given the symbol  $\epsilon$ .

The Beer-Lambert law is often used in quantitative IR analysis using peakheights in the absorbance spectrum as values for  $A$ , frequently after baseline correction. Peakheights, however, are strongly dependent on instrumental resolution and an alternative measure of the absorbance of a band is its integrated intensity, which is the intensity integrated over the whole IR band. The integrated intensity may be expressed using the integrated absorptivity  $\mathcal{A}$ , the absorptivity integrated over the whole IR band, given by

$$\mathcal{A} = \int_{\text{band}} a(\tilde{\nu}) d\tilde{\nu} \quad [55]$$

where  $a(\tilde{\nu})$  has been written to highlight the dependence of the absorptivity on wave number. Due to the integration with respect to the wave number the dimensions of the integrated absorptivity are that of the absorptivity divided by the dimension of length. Using eqn [54], the last equation may be expressed as

$$\mathcal{A} = \frac{1}{Cl} \int_{\text{band}} \log_{10} \left( \frac{I_0}{I} \right) d\tilde{\nu} \quad [56]$$

While the peakarea is a better measure of band intensity than peakheight in theory, the effect of absorption by neighboring bands leads to baseline errors that affect the calculation of area more adversely than peakheight. It is probably true to say that most contemporary quantitative determinations are made using peakheight.

The major interaction between the electromagnetic radiation and a molecule is due to the interaction of the electric field of the former,  $E$ , with the dipole moment of the latter,  $\mu$ . (Magnetic interactions are much smaller and generally are not important in

vibrational spectroscopy, although they are responsible for IR circular dichroism.) The interaction gives rise to a time-dependent perturbation of the quantum states of a molecule equal to  $-\mathbf{\mu} \cdot \mathbf{E}$ . Using the results of time-dependent perturbation theory (Fermi's Golden Rule) it can be shown that the integrated absorptivity of a transition between initial state  $\langle i|$  and final state  $\langle f|$  for an isotropic system is given by

$$\mathcal{A} = \frac{N_A 2\pi^2 \bar{\nu}_{if}}{3\epsilon_0 h c \ln_e 10} |\langle i|\mathbf{\mu}|f\rangle|^2 \quad [57]$$

where  $\langle i|$  and  $\langle f|$  are the initial and final states of the transition,  $\mathbf{\mu}$  is the molecular dipole moment operator,  $N_A$  is Avogadro's number,  $\bar{\nu}_{if}$  is the wave number corresponding to the band center,  $\epsilon_0$  is the permittivity of free space,  $h$  is Planck's constant, and  $c$  is the speed of light. The quantity

$$\langle i|\mathbf{\mu}|f\rangle \left[ \equiv \int \Psi_i^0 \mathbf{\mu} \Psi_f d\tau \right] \quad [58]$$

is known as the electric dipole transition moment and its magnitude determines the intensity of a transition.

The appearance of  $\ln_e 10$  in eqn [57] is to be consistent with the definition of absorbance using base-10 logs. Often the equation will be seen without divisor, in which case it should be noted that the absorptivity has been defined using the natural log scale.

It should be noted that eqn [57] strictly only applies to dilute gases. In condensed phases refractive index effects become important.

Equation [57] often appears in Gaussian units. The Gaussian version is obtained by replacing  $\epsilon_0$  by  $1/4\pi$  to give

$$\mathcal{A} = \frac{N_A 8\pi^3 \bar{\nu}_{if}}{3hc \ln_e 10} |\langle i|\mathbf{\mu}|f\rangle|^2 \quad [59]$$

The transition electric dipole moment in eqn [57] can be developed by invoking the Born–Oppenheimer approximation to express the total molecular wave function as a product of electronic and vibrational parts. (Rotational wave functions do not have to be included here since eqn [57] refers to an isotropic system. That is, the equation is a result of a rotational average which is equivalent to a summation over all the rotational states involved in the transition.) A general molecular state can now be expressed as the product of vibrational and electronic parts. Assuming that the initial and final electronic states are the ground state  $|e_g\rangle$ ,

$$|i\rangle = |i_{\text{vib}}\rangle |e_g\rangle \quad [60a]$$

$$|f\rangle = |f_{\text{vib}}\rangle |e_g\rangle \quad [60b]$$

and the transition moment becomes

$$\begin{aligned} \langle i|\mathbf{\mu}|f\rangle &= \langle v_i|\langle e_g|\mathbf{\mu}|e_g\rangle|v_f\rangle \\ &= \langle v_i|\mathbf{\mu}_e|v_f\rangle \end{aligned} \quad [61]$$

where  $|v_i\rangle$  and  $|v_f\rangle$  are the initial and final vibrational states, respectively, and  $\mathbf{\mu}_e$  is the permanent dipole moment of the molecule. The permanent dipole moment is now treated as a parametric function of the normal coordinates and expressed as a power series

$$\begin{aligned} \langle v_i|\mathbf{\mu}_0 + \sum_{p=1}^{3N-6} \left( \frac{\partial \mathbf{\mu}}{\partial Q_p} \right)_0 Q_p \\ + \frac{1}{2} \sum_{p=1}^{3N-6} \sum_{r=1}^{3N-6} \left( \frac{\partial^2 \mathbf{\mu}}{\partial Q_p \partial Q_r} \right)_0 Q_p Q_r + \dots |v_f\rangle \end{aligned} \quad [62]$$

Ignoring the quadratic terms (assuming the system is electrically harmonic) gives

$$\langle v_i|\mathbf{\mu}_e^0|v_f\rangle + \sum_{p=1}^{3N-6} \langle v_i|\left( \frac{\partial \mathbf{\mu}_e}{\partial Q_p} \right)_0 Q_p|v_f\rangle \quad [63]$$

The total vibrational wave function  $\langle v|$  is given by the product of the  $3N-6$  normal coordinate wave functions

$$\langle v| = \langle v_1|\langle v_2|\langle v_3|\dots\langle v_{3N-6}| \quad [64]$$

where  $\nu_p$  is the vibrational quantum number of the  $p$ th normal vibration.

The total vibrational energy is given by

$$\begin{aligned} G(\nu_1, \nu_2 \dots \nu_{3N-6}) &= \left( \nu_1 + \frac{1}{2} \right) \tilde{\nu}_1 + \left( \nu_2 + \frac{1}{2} \right) \tilde{\nu}_2 \\ &+ \dots + \left( \nu_{3N-6} + \frac{1}{2} \right) \tilde{\nu}_{3N-6} \end{aligned} \quad [65]$$

Let the vibrational ground state  $|0\rangle$  be represented by

$$|0\rangle = \langle 0_1|\langle 0_2|\langle 0_3|\dots\langle 0_{3N-6}| \quad [66]$$

and the state with the  $p$ th normal mode in the  $\nu_p = 1$  state be represented by

$$|1_p\rangle = \langle 0_1|\langle 0_2|\langle 0_3|\dots\langle 1_p|\dots\langle 0_{3N-6}| \quad [67]$$

Using the properties of harmonic oscillator wave functions (the Hermite polynomials) that

$$\langle 0|Q_p|1_r\rangle = \left( \frac{h}{8\pi^2\nu} \right)^{1/2} \delta_{pr} \quad [68]$$

where  $\delta_{pr}$  is the Kronecker delta (which is unity if  $p=r$  and zero otherwise), and

$$\langle 0|1_p\rangle = 0 \quad [69]$$

Eqn [63] becomes

$$\left(\frac{h}{8\pi^2\nu_p}\right)^{1/2}\left(\frac{\partial\mu}{\partial Q_p}\right)_0 \quad [70]$$

Substituting in eqn [57],

$$\mathcal{A} = \frac{N_A}{12\epsilon_0 c^2 \ln_e 10} \left| \left(\frac{\partial\mu}{\partial Q_p}\right)_0 \right|^2 \quad [71]$$

$$\left| \left(\frac{\partial\mu}{\partial Q_p}\right)_0 \right| = \left( \frac{12\epsilon_0 c^2 \ln_e 10}{N_A} \right)^{1/2} \mathcal{A}^{1/2} \quad [72]$$

Note that the sign of the derivative of the dipole moment cannot be determined directly by measuring the integrated absorbance of an IR band.

Equation [71] shows the origin of the gross selection rule that the dipole moment of a molecule must change in the course of a normal coordinate excursion for the vibration to absorb IR radiation. The transition moment in eqn [57] is only nonzero for the case where only one vibration is excited and for the situation in which the quantum number of the vibration involved changes by  $\pm 1$ . Hence the selection rule given earlier in eqn [17].

### Anharmonic Effects in Spectra of Polyatomic Molecules

**Combination and difference bands** Besides overtones, anharmonicity also leads to the appearance of combination bands and difference bands in the IR spectrum of a polyatomic molecule. In the harmonic case, only one vibration may be excited at a time (the transition dipole moment integral vanishes when the excited state is given by a product of more than one Hermite polynomial corresponding to different excited vibrations). This restriction is relaxed in the anharmonic case and one photon can simultaneously excite two different fundamentals. A weak band appears at a frequency approximately equal to the sum of the fundamentals involved. (Only approximately because the final state is a new one resulting from the anharmonic perturbation to the potential energy mixing the two excited state vibrational wave functions.)

A difference band is the result of a transition from an excited level of one normal vibration to a higher energy level of another vibration. The frequency of the difference band occurs at exactly the difference in the frequencies of direct transitions to the excited states involved from the vibrational ground state. ('Exactly' equal in this case because no new vibrational state is involved.)

Because difference bands originate from thermally populated excited states, they will be more frequently observed at lower frequencies and increase in intensity as the temperature is raised. (Transitions which occur from states other than the ground state are known as hot bands. They are generally weak in mid-IR spectra at room temperature due to vibrational energy gaps which are relatively large compared to  $kT$ ).

**Fermi resonance** If an overtone or combination transition occurs with nearly the same frequency as a fundamental transition of the same symmetry, then the anharmonic term in the potential function causes the two vibrations to interact or 'mix'. This is known as Fermi resonance. The extent of the mixing increase as the frequency difference decreases. The result is that the overtone or combination band acquires intensity through having some of the fundamental vibration mixed into it. Fermi resonance causes the two bands involved to split apart from the positions they would have occupied had no interaction occurred.

**Symmetry of molecular vibrations** Every normal coordinate of a molecule must transform according to an irreducible representation of the molecular point group. If the molecular geometry is known, then it is a routine matter to use the methods of group theory to deduce how many vibrations occur for each irreducible representation. The procedure is to assign three Cartesian displacement coordinates to each atom and to use the  $3N$  coordinates as basis functions for a  $3N \times 3N$  matrix representation of the point group. A reducible representation is then obtained by taking the trace of these matrices. This representation is then reduced to a sum of irreducible representations using

$$N_i = \frac{1}{h} \sum_{\hat{R}} \chi_i(\hat{R}) \chi_{\text{red}}(\hat{R}) \quad [73]$$

where  $N_i$  is the number of times that symmetry species  $i$  occurs,  $h$  is the order of the group,  $\chi_i(\hat{R})$  is the character associated with symmetry species  $i$  and symmetry operation  $\hat{R}$ , and  $\chi_{\text{red}}(\hat{R})$  is the character of the reducible representation associated with symmetry with symmetry operation  $\hat{R}$ .

One must then remove the irreducible representation which result from the three translational and three rotational degrees of freedom (two for a linear molecule). These can be identified from the character table of the molecular point group: the translational degrees of freedom transform as the functions  $x$ ,  $y$ , and  $z$  (denoted  $T_x$ ,  $T_y$ ,  $T_z$  or  $x$ ,  $y$ ,  $z$  in the character tables); and the rotational degrees of freedom transform as the components of an axial vector (denoted  $R_x$ ,  $R_y$ , and  $R_z$  in the character tables). The

method is illustrated below for a bent triatomic molecule which belongs to the  $C_{2v}$  point group.

**Figure 12A** shows the molecule with three Cartesian coordinates associated with each atom. **Figure 12B** shows the effect of  $C_2$  rotation on the coordinates. This transformation can be described in matrix form as

$$\begin{array}{cccccccccccc}
 \Delta x_1 & -\Delta x_3 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 & \Delta x_1 \\
 \Delta y_1 & -\Delta y_3 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & 0 & \Delta y_1 \\
 \Delta z_1 & \Delta z_3 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & \Delta z_1 \\
 \Delta x_2 & -\Delta x_2 & 0 & 0 & 0 & -1 & 0 & 0 & 0 & 0 & 0 & \Delta x_2 \\
 C_2 \Delta y_2 = -\Delta y_2 & = 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 & 0 & 0 & \Delta y_2 \\
 \Delta z_2 & -\Delta z_2 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & \Delta z_2 \\
 \Delta x_3 & -\Delta x_1 & -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & \Delta x_3 \\
 \Delta y_3 & -\Delta y_1 & 0 & -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & \Delta y_3 \\
 \Delta z_3 & \Delta z_1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & \Delta z_3
 \end{array} \quad [74]$$

From eqn [74] it can be seen that the trace of the  $C_2$  matrix  $\chi(C_2)$  is  $-1$ . Using the same procedure for the other symmetry operations, the complete reducible representation formed from the traces of the matrices corresponding to all the symmetry operations of the  $C_{2v}$  group is given by

$$\begin{array}{cccc}
 \chi_{\text{red}}(E) & \chi_{\text{red}}(C_2) & \chi_{\text{red}}(\sigma_v) & \chi_{\text{red}}(\sigma_{v'}) \\
 \Gamma_{\text{red}} & 9 & -1 & 1 & 3
 \end{array}$$

**Figure 12** (A) Cartesian displacement coordinates of symmetric triatomic molecules. (B) Cartesian coordinates after  $C_2$  rotation.

This representation can be reduced using eqn [73] and the information in  $C_{2v}$  character table. For example, the number of times  $N_{A_1}$  (the  $A_1$  irreducible representation) is contained in  $\Gamma_{\text{red}}$  is given by

$$N_{A_1} = \frac{1}{4}[(1)(9) + (1)(-1) + (1)(1) + (1)(3)] = 3$$

The same procedure can be carried out for each symmetry species of  $C_{2v}$  to give

$$\Gamma_{\text{red}} = 3A_1 + A_2 + 2B_1 + 3B_2 \quad [75]$$

From the  $C_{2v}$  character table, the three translations span  $A_1$ ,  $B_1$ , and  $B_2$ , and the three rotations span  $A_2$ ,  $B_1$ , and  $B_2$ . If these are taken away from eqn [75], this leaves  $2A_1$  and  $B_2$ . The three normal vibrations of the bent triatomic molecule, therefore, span these irreducible representations. (See **Figure 9**: the anti-symmetric stretch is  $B_2$ .)

This method may be simplified by noting that only Cartesian coordinates associated with atoms whose positions are unchanged by a symmetry operation may contribute to the trace of a matrix. If a symmetry operation  $\hat{R}$  leaves the position of  $U_{\hat{R}}$  atoms unchanged, then it can be shown that the character of the transformation matrix for not including transformations and rotations is given by

$$\chi(\hat{R}) = (U_{\hat{R}} - 2)(1 + 2 \cos \phi) \quad [76a]$$

for proper rotations, and

$$\chi(\hat{R}) = U_{\hat{R}}(-1 + 2 \cos \phi) \quad [76b]$$

for improper rotations (reflection, rotation–reflection, inversion) where  $\phi$  is the angle through which the molecule is rotated. (Inversion through the center of symmetry is equivalent to an improper rotation through  $180^\circ$ , a reflection in a plane of symmetry is an improper rotation through  $0^\circ$ , and the identity element is a proper rotation through  $0^\circ$ .)

For the molecule  $\text{ClCH}_3$ , which belongs to the point group  $C_{3v}$ , the number of atoms left unchanged

by the three symmetry operations  $I$ ,  $C_3$ , and  $\sigma_v$  is

$$U_I = 5, \quad U_{C_3} = 2, \quad U_{\sigma_v} = 3 \quad [77]$$

Using eqn [77] in eqn [76] gives:

$$\Gamma_{\text{red}} \begin{array}{ccc} \chi(I) & \chi(C_3) & \chi(\sigma_v) \\ 9 & 0 & 3 \end{array}$$

This representation can be reduced using eqn [73] to give  $3A_1 + 3E$ . Thus,  $\text{ClCH}_3$  ( $3N - 6 = 9$ ) has three totally symmetric vibrations and three doubly degenerate vibrations.

### Symmetry Selection Rules

Using eqn [61] for a fundamental vibration  $Q_p$  it can be seen that the band intensity is proportional to the following transition dipole moment integral:

$$\langle 0 | \mu_\alpha | 1_p \rangle, \quad \alpha = x, y, z \quad [78]$$

Unless the integrand is totally symmetrical the integral will be identically zero. Since the vibrational ground state is always totally symmetric, an IR fundamental will only be allowed when one or more components of the dipole moment operator span the same irreducible representation as the normal vibration. The components of the dipole moment operator  $\mu_x$ ,  $\mu_y$ , and  $\mu_z$  span the same irreducible representations as the functions  $x$ ,  $y$ , and  $z$ , respectively. Hence a fundamental vibration will only be allowed if it spans the same irreducible representations as  $x$ ,  $y$ , or  $z$  ( $T_x$ ,  $T_y$ , or  $T_z$ ).

It was shown before that a bent triatomic molecule undergoes two  $A_1$  and one  $B_2$  vibrations. Inspection of the  $C_{2v}$  character table reveals that  $z$  spans  $A_1$  and  $y$  spans  $B_2$ . Therefore, all the vibrations are allowed. This is not to say that all three bands will appear. The magnitude of the transitions dipole moments may be so small that a transition may not be observed.

If a molecule has several possible structures which belong to different molecular point groups then the methods above can be used for structure elucidation, especially in conjunction with the results of the analogous analysis for vibrational Raman bands. For example, if a molecule is known to have the molecular formula  $\text{AB}_4$ , a group theoretical analysis predicts that a tetrahedral molecule would have two active IR fundamentals, whereas a square planar molecule would have three.

### Infrared Spectroscopy of Crystals

In molecular crystals the molecules are held together by van der Waals forces, and since these bonds are

very much weaker than chemical bonds, the molecular vibrations are normally very similar to those of the free molecule. However, the crystal environment will generally lower the symmetry of the molecule, with the result that the degeneracy of vibrations may be lifted and vibrations, which were forbidden in the free molecule can become allowed in the crystal so that extra bands can appear. The formal treatment of the symmetry of vibrations in molecular crystals is obtained by considering the local symmetry in the crystal unit cell (site group analysis). A more complete theory, which includes lattice modes, is provided by factor group analysis.

Vibrations due to the crystal lattice occur in the far-IR from  $\sim 50$  to  $400 \text{ cm}^{-1}$ . It is possible to distinguish between some molecular and lattice vibrations using the fact that molecular vibrations are relatively insensitive to the effects of temperature and pressure while the frequencies of lattice vibrations generally increase with a decrease in temperature and with an increase in pressure.

### Infrared Linear Dichroism

For oriented single crystals there will generally be a difference in the absorption between two linearly polarized IR beams that are mutually orthogonal and orthogonal to the direction of propagations. The dichroic ratio is defined as

$$R = \frac{\int_{\text{band}} \varepsilon_{\parallel}(\tilde{\nu}) d\tilde{\nu}}{\int_{\text{band}} \varepsilon_{\perp}(\tilde{\nu}) d\tilde{\nu}} \quad [79]$$

where  $\varepsilon_{\parallel}$  and  $\varepsilon_{\perp}$  refer to polarization parallel and perpendicular to the crystal axis, respectively. If the symmetry of the crystal is known, then the dichroic ratio can give information about the symmetry of the vibration.

### Calculation of Normal Coordinates

Given the molecular geometry and a set of force constants for a polyatomic molecule, it is a routine matter to calculate the normal coordinates, a procedure known as normal coordinate analysis. Suites of computer programs are readily available that will calculate vibrational frequencies and the internal coordinate composition of each normal vibration. Most of the early calculation of vibration frequencies were made by Wilson's FG-matrix method, which is briefly summarized below. Today, a number of alternative techniques based on semiempirical methods, molecular mechanics, or density functional theory are also available, in convenient commercial software packages.

In the Wilson FG-matrix method, the problem is framed in internal coordinates rather than in

Cartesian displacement coordinates because the force constants involved are more meaningful in relation to the chemical structure of the molecule and are more readily transferred between similar molecules. Also, the theoretical procedure using internal coordinates are such that the translational and rotational motion of a molecule are automatically taken into account.

### The F Matrix

In the harmonic approximation the potential energy of a molecule can be expressed as

$$2V = \sum_{ij} F_{ij} R_i R_j = \tilde{\mathbf{R}} \mathbf{F} \mathbf{R} \quad [80]$$

where  $R_i$  are the internal coordinates,  $\mathbf{F}$  is the  $3N-6 \times 3N-6$  matrix formed by the force constants,  $\mathbf{R}$  is a column vector formed by the internal coordinates and  $\tilde{\mathbf{R}}$  is its transpose. (In order to have the same dimensions for all coordinates, and therefore all the force constants, the angle bending internal coordinates are sometimes scaled with a bond length, e.g., in water the angle bend coordinate  $\Delta\alpha$  would become  $r\Delta\alpha$  where  $r$  is the O-H bond length.)

Collectively, the  $F_{ij}$  are known as the force field of the molecule. These force constants are treated as empirical parameters whose values are optimized by obtaining the best fit of calculated to experimental results for vibrational frequencies, Coriolis coupling constants (which govern a type of coupling between rotational and vibrational motion), centrifugal distortion constants, and mean-square amplitudes of vibration. The simplest force field neglects all off-diagonal or interaction force constants. This valence force field (VFF), in general, gives poor results due to the poor number of adjustable parameters (the non-zero force constants).

In the generalized valence force field (GVFF) there is no neglect of the off-diagonal terms. However, for molecules of any appreciable size the number of force constants to be determined becomes too large to evaluate them with accuracy. Hence the simplified general valence force field (SGVFF) is frequently used in which all off diagonal force constants are set to zero except those involving two internal coordinates with common atoms.

The Urey-Bradley force field (UBFF) is also commonly used. This consists of diagonal stretch and bend force constants together with repulsive force constants representing nonbonded atom-atom interaction.

### The G Matrix

The kinetic energy part of the vibrational problem is expressed in the  $\mathbf{G}$  matrix whose elements depend

on atomic masses and molecular geometry. It can be shown that the vibrational kinetic energy  $T$  is given by

$$2T = \dot{\mathbf{R}} \mathbf{G}^{-1} \dot{\mathbf{R}} \quad [81]$$

where a dot denotes the time derivative.

The elements of the  $\mathbf{G}$  matrix are given in Figure 13.

As an example, the  $\mathbf{G}$  matrix for a nonlinear triatomic molecule (Figure 14) is given by

$$\mathbf{G} = \begin{bmatrix} \mu_1 + \mu_3 & \mu_3 \cos \phi & -\frac{\mu_3 \sin \phi}{r_2} \\ \mu_3 \cos \phi & \mu_2 + \mu_3 & -\frac{\mu_3 \sin \phi}{r_1} \\ -\frac{\mu_3 \sin \phi}{r_2} & -\frac{\mu_3 \sin \phi}{r_1} & \frac{\mu_1}{r_1^2} + \frac{\mu_2}{r_2^2} + \mu_3 \left( \frac{1}{r_1^2} + \frac{1}{r_2^2} - \frac{2 \cos \phi}{r_1 r_2} \right) \end{bmatrix} \quad [82]$$

(The exact form of the elements of  $\mathbf{G}$  depends on whether scaled or unscaled coordinates are being used. The above is for unscaled.)

### The Secular Equation

The relationship between internal coordinates and normal coordinates is defined as

$$\mathbf{R} = \mathbf{L} \mathbf{Q} \quad [83]$$

It can be shown that the matrix vibrational secular equation is given by

$$\mathbf{G} \mathbf{F} \mathbf{L} = \mathbf{L} \mathbf{A} \quad [84]$$

where  $\mathbf{A}$  is the diagonal eigenvalue matrix and  $\mathbf{L}$  is the matrix of eigenvectors of the matrix product  $\mathbf{G} \mathbf{F}$ . This last equation is solvable when

$$|\mathbf{G} \mathbf{F} - \mathbf{E} \lambda| = 0 \quad [85]$$

where  $\mathbf{E}$  is the unit matrix and  $\lambda$  is a root of the secular polynomial. There will be  $3N-6$  non-zero roots, which are equal to the squares of vibrational angular frequencies. So the problem is essentially the diagonalization of  $\mathbf{G} \mathbf{F}$ , a process which is easily carried out by computer using numerical methods.

From eqn [83] we have

$$\mathbf{Q} = \mathbf{L}^{-1} \mathbf{R} \quad [86]$$

so that the elements of  $\mathbf{L}^{-1}$  can be used to obtain a picture of the normal vibration in terms of the internal coordinates. However, the reported results of a normal coordinate analysis often include the potential energy distribution (PED) for this information. The PED is the fraction of the potential energy

**Figure 13** Representation of common elements of the **G** matrix. Key: atoms common to both coordinates are double circles in horizontal line; number of common atoms as superscript; atoms above horizontal belong to first coordinate; those below belong second;  $\binom{n}{m}$  –  $n$  and  $m$  are numbers of (noncommon) atoms above horizontal on left and below horizontal on left, respectively.  $c$ ,  $\cos$ ;  $s$ ,  $\sin$ ;  $\rho_{\alpha\beta} = 1/r_{\alpha\beta}$ ;  $\mu_{\alpha} = 1/\text{mass } \alpha$ .

**Figure 14** Nonlinear triatomic molecule.

of a normal mode contributed by each force constant  $F_{ij}$ . The diagonal elements of this distribution for the major components of a normal vibration are quoted as a percentage. For vibration  $Q_p$  and internal coordinate  $R_i$

$$\text{PED}(R_i) = \left( \frac{100F_{ii}L_{ip}^2}{\sum_i F_{ii}L_{ip}^2} \right) \% \quad [87]$$

The sum of the diagonal elements in the PED can exceed 100% due to the neglect of the off-diagonal contributions.

### Use of Symmetry

When a molecule possesses symmetry the vibrational problem may be simplified by transforming the internal coordinates to symmetry coordinates. A vibration of a certain symmetry will be composed solely of symmetry coordinates belonging to the same symmetry species.

The transformation to symmetry coordinates  $\mathbf{R}^S$  is given by

$$\mathbf{R}^S = \mathbf{U}\mathbf{R} \quad [88]$$

The symmetry coordinates and hence the coefficients of the (unitary) symmetrization matrix are obtained by applying symmetry projection operators to the internal coordinates. For irreducible

representation  $i$

$$R_i^S = N \sum_{\hat{R}} \chi_i(\hat{R}) \hat{R} \times R \quad [89]$$

where  $N$  is a normalization factor.

A similarity transformation using  $U$  is carried out on the  $F$  and  $G$  matrices

$$F^S = UF\tilde{U} \quad [90a]$$

$$G^S = UG\tilde{U} \quad [90b]$$

The symmetrization process produces the block-factored matrices  $F^S$   $G^S$ . Hence the product  $G^S F^S$  will be block-factored and each block may be diagonalized separately.

### Isotopic Substitution in Polyatomic Molecules: The Teller–Redlich Product Rule

Observation of the changes in frequency that occur in a vibrational spectrum as a result of isotopic substitution of one or more atoms is an important method for assessing the accuracy of molecular force fields. Isotopic substitution is also important for making band assignments in large molecules: the only vibrations to be shifted will be those involving the isotopically substituted atoms.

For isotopic substitution in which the molecular point group is unchanged, the Teller–Redlich product rule links the two sets of vibrational frequencies. There is one product rule for each symmetry species of the molecule as follows

$$\frac{\Pi_V}{\Pi_{V'}} = \left\{ \left( \frac{M}{M'} \right)^t \left( \frac{I_x}{I'_x} \right)^{r_x} \left( \frac{I_y}{I'_y} \right)^{r_y} \left( \frac{I_z}{I'_z} \right)^{r_z} \Pi \left( \frac{m'}{m} \right)^a \right\}^{1/2} \quad [91]$$

where a prime is used to distinguish properties of the two molecules and  $\Pi$  denotes a product. The products on the left-hand side include all vibrations in the particular symmetry species to which the equation applies.  $M$  is the molecular mass;  $t$  is the number of

translations belonging to the symmetry species in question (which can be deduced using the methods described in the section on symmetry);  $I_x$ ,  $I_y$ , and  $I_z$  are moments of inertia about the three Cartesian axes;  $r_x$ ,  $r_y$ , and  $r_z$  are 1 if the respective rotation belongs to the symmetry species concerned and 0 otherwise;  $m$  is the mass of an atom which is a member of a set of symmetrically equivalent atoms and  $a$  is the number of external (rotational and translational) symmetry coordinates which these atoms give rise to. The product on the right-hand side involves all sets of symmetrically equivalent atoms.

### Introduction

Since an infrared spectrum can be recorded from almost any material, infrared spectroscopy is an

extremely important analytical technique. Mid-infrared spectroscopy is used extensively in applications involving qualitative analysis, providing either functional group or structural information about a sample or fingerprinting (identifying) a material. There is also widespread use of the technique for quantitative purposes, since the absorbance of a band is proportional to the concentration of the species that gives rise to the absorption band.

representation  $i$

$$R_i^S = N \sum_{\hat{R}} \chi_i(\hat{R}) \hat{R} \times R \quad [89]$$

where  $N$  is a normalization factor.

A similarity transformation using  $U$  is carried out on the  $F$  and  $G$  matrices

$$F^S = UF\tilde{U} \quad [90a]$$

$$G^S = UG\tilde{U} \quad [90b]$$

The symmetrization process produces the block-factored matrices  $F^S$   $G^S$ . Hence the product  $G^S F^S$  will be block-factored and each block may be diagonalized separately.

### Isotopic Substitution in Polyatomic Molecules: The Teller–Redlich Product Rule

Observation of the changes in frequency that occur in a vibrational spectrum as a result of isotopic substitution of one or more atoms is an important method for assessing the accuracy of molecular force fields. Isotopic substitution is also important for making band assignments in large molecules: the only vibrations to be shifted will be those involving the isotopically substituted atoms.

For isotopic substitution in which the molecular point group is unchanged, the Teller–Redlich product rule links the two sets of vibrational frequencies. There is one product rule for each symmetry species of the molecule as follows

$$\frac{\Pi_V}{\Pi_{V'}} = \left\{ \left( \frac{M}{M'} \right)^t \left( \frac{I_x}{I'_x} \right)^{r_x} \left( \frac{I_y}{I'_y} \right)^{r_y} \left( \frac{I_z}{I'_z} \right)^{r_z} \Pi \left( \frac{m'}{m} \right)^a \right\}^{1/2} \quad [91]$$

where a prime is used to distinguish properties of the two molecules and  $\Pi$  denotes a product. The products on the left-hand side include all vibrations in the particular symmetry species to which the equation applies.  $M$  is the molecular mass;  $t$  is the number of

translations belonging to the symmetry species in question (which can be deduced using the methods described in the section on symmetry);  $I_x$ ,  $I_y$ , and  $I_z$  are moments of inertia about the three Cartesian axes;  $r_x$ ,  $r_y$ , and  $r_z$  are 1 if the respective rotation belongs to the symmetry species concerned and 0 otherwise;  $m$  is the mass of an atom which is a member of a set of symmetrically equivalent atoms and  $a$  is the number of external (rotational and translational) symmetry coordinates which these atoms give rise to. The product on the right-hand side involves all sets of symmetrically equivalent atoms.

### Introduction

Since an infrared spectrum can be recorded from almost any material, infrared spectroscopy is an

extremely important analytical technique. Mid-infrared spectroscopy is used extensively in applications involving qualitative analysis, providing either functional group or structural information about a sample or fingerprinting (identifying) a material. There is also widespread use of the technique for quantitative purposes, since the absorbance of a band is proportional to the concentration of the species that gives rise to the absorption band.

This article covers the preparation and presentation methods, both traditional and the more recently developed, used in sample analyses by mid-infrared spectroscopy. It focuses more on the so-called macro-sampling techniques, and does not cover in detail some of the sample presentation methods, for example diamond-window compression cells (see example in Figure 7), more particularly used nowadays in studies made using an infrared microscope; many of the microsampling techniques are, however, merely adaptations of the macrosampling techniques.

A prime consideration in sample presentation has to be the purpose of the study. For instance in solids, one must decide whether the chemical structure of the solid is of singular importance, or whether its physical characteristics are of interest. If, for example, the requirement is to study polymorphism in drugs or minerals, or perhaps crystallinity or molecular orientation in polymers, then the integrity of these properties will need to be maintained throughout sample preparation, presentation, and measurement. Sample presentation methods that provide simple, rapid generic identification may prove inadequate for more detailed substructure investigations, such as compositional or conformational analyses.

The specimen or specimens analyzed must be representative of the sample in the context of the study purpose or problem definition, particularly if the sample is heterogeneous. Sampling techniques that are inherently surface sensitive may not yield spectra that are characteristic of the bulk of the sample. Quantitative precision is likely to impose greater restrictions on the choice of the sample preparation method than simple generic fingerprinting studies, since reproducibility will be an essential requirement for most product quality assurance applications.

## Sample Presentation and Preparation Techniques

The procedures, requirements, and some limitations of the various presentation methods as practiced in the laboratory are considered in detail in this section. Samples are categorized as gases, liquids, paste-like, or solids.

### Gases

In the laboratory, the mid-infrared absorption spectra of gases are usually measured in gas-tight transmission cells. Gas cells are essentially gas-tight containers fitted with: (1) infrared transparent windows to enable the radiation to enter and exit the container, and (2) a means for introducing, pressurizing, and

evacuating the gas. They vary from a cylinder of a few centimeters pathlength, typically 10 cm and constructed from Pyrex<sup>®</sup> or stainless steel, with windows at each end, to compact long pathlength cells which have internal gold-coated mirrors for multipassing the radiation over many meters pathlength through the gas sample (see Figure 1).

Beer's law for a gas may be represented as

$$A = kl\rho$$

where,  $A$  is the absorbance,  $k$  the absorptivity,  $l$  the pathlength, and  $\rho$ , which replaces the concentration in the usual Beer's law notation, is the pressure, or partial pressure of the gas in a mixture of gases.

The absorbance of a component in a gas mixture depends not only on its partial pressure, but is also a function of the total pressure. Molecular collisions will broaden the rotational fine structure of the gas-phase bands, a phenomenon known as pressure broadening. So, although 50 mm Hg or less is a pressure at which many gases in a 10-cm pathlength cell yield useful spectra, a common practice is to keep the total pressure constant. This is achieved by adding a nonabsorbing gas such as nitrogen up to a standard pressure, such as 760 mm Hg.

### Liquids

Liquids may be sampled as neat liquids or in solution. A mid-infrared transmission spectrum sufficient for chemical identification may often be recorded from a capillary layer of a nonvolatile, pure liquid. This may be prepared simply from a drop of the liquid that has been sandwiched between a pair of mid-infrared transparent windows clamped together, which is also resistant to attack by the liquid. A more reproducible (and safer) practice, however, is to use an appropriate pathlength cell. Whichever method is selected, the specimen examined must be free from bubbles. For strongly absorbing liquids and some quantitative applications, a more efficient approach may be to use an appropriate infrared internal reflection technique accessory.

A liquid sample, either neat or as a solution, may be examined contained within a sealed or demountable cell. Cells are essential for transmission measurements of volatile liquids and samples in solution, and imperative for the majority of quantitative determinations. While contained gases are usually examined in cells of several centimeters to several meters pathlength, liquid and solid samples generally require a very much shorter thickness. Cells are available commercially in two types (see Figure 2). Fixed pathlength cells provide the optimal means of examining reproducibly a series of liquid samples

**Figure 1** Examples of gas cells for mid-infrared transmission measurements: (A) photograph of a multiple-pass gas cell ('Long Path Minicell'), with a high path-to-volume (530 ml) ratio. Allows paths from 1.2 m (eight passes) to 7.2 m (48 passes); (B) schematic of a multipass cell with transfer optics for use in a center-focus sample compartment; (C) and (D) photographs of Pyrex<sup>®</sup> and stainless steel bodied 10-cm pathlength cells, respectively. that are not too viscous, or corrosive or damaging to the cell windows or body. A pathlength of 0.1 mm will provide a sample thickness that is useful for observing the spectral detail of many neat nonpolar liquids. However, for polar molecules, if all the absorption bands are to be surveyed, it will usually be necessary to significantly reduce the pathlength to less than 0.025 mm, and in some instances to less than 0.01 mm. A typical macrosample cell of pathlength 0.1 mm will require about  $\sim 0.3$  ml to fill. Cavity cells of volumes as low as  $0.2 \mu\text{l}$  are available commercially for microsampling, although these are normally used in combination with a beam-condensing optical arrangement. A range of window materials is employed according to their infrared transmission characteristics and the properties of the liquid sample. Among the most common for mid-infrared are KBr, NaCl, CsI, and ZnSe, with BaF<sub>2</sub> and CaF<sub>2</sub> being frequently used because of their mechanical strength and insolubility in water, although these offer reduced spectral coverage. Polyethylene and TPX<sup>®</sup> (poly(4-methyl pent-1-ene)) are

frequently used window materials for the far-infrared region.

Maintaining and cleaning thin cells can be troublesome; in particular traces of viscous liquids may prove extremely difficult to remove. In these circumstances, a demountable cell (see Figure 2), which can be dismantled for cleaning, may be preferable. A range of spacers of differing uniform thickness is available to set the cell pathlength. For a cell that has flat, polished, and parallel windows its pathlength may be determined from a recording of the interference fringe pattern generated by the empty cell. Constructive and destructive interference between the primary transmitted beam and that which has been back reflected from within the cell results in a sinusoidal variation of transmitted intensity. A cell's pathlength (thickness)  $d$ , is calculated from

$$d = \frac{n}{2(v_1 - v_2)}$$

where,  $n$  is the number of complete fringes between wave numbers  $v_1$  and  $v_2$ .

**Figure 2** Examples of liquid cells for mid-infrared transmission measurements: (A) sealed vacuum tight liquid cell with an amalgam spacer for FT-IR, (B) exploded view of a liquid cell design with a rectangular aperture for use with a dispersive infrared spectrometer, and (C) semipermanent (dismountable) liquid cell for FT-IR with Teflon<sup>®</sup> spacer, and fitted with a Luer fitting and Teflon<sup>®</sup> plugs. (Reproduced by kind permission of Specac Ltd., Orpington, Kent, UK.)

Some of the problems associated with routine use of thin transmission cells may be circumvented through use of internal reflection accessories.

In mid-infrared internal reflection spectroscopy, often called attenuated total reflection (ATR) spectroscopy, the surface of a sample is placed in intimate contact with a higher refractive index, infrared transparent internal reflection element, and its spectrum recorded with infrared radiation that is incident through the reflection element at an angle greater than the critical angle. Common internal reflection elements are made from ZnSe, Ge, and diamond. The infrared radiation incident through the reflection element is totally internally reflected at the reflection element-sample boundary; the infrared beam may, however, be considered to penetrate a short distance into the sample and be attenuated by the absorption characteristics of the surface layer in contact with the reflection element; the penetration depth of the mid-infrared radiation into the sample is typically of the order of 0.3–3  $\mu\text{m}$ , which is wavelength dependent, and also dependent on the angle of incidence and the refractive indexes of both the reflection element material and the sample. Common designs for the analysis of liquids using Fourier transform infrared (FT-IR) spectroscopy come in essentially two types; those commonly referred to as horizontal ATR (H-ATR) units (see Figure 3), and those based on rod- or cylinder-like reflection elements, which are incorporated either into a dip-in probe or mounted through a chamber to contain the liquid. These units

**Figure 3** Photograph of horizontal (overhead) multiple internal reflection accessory. (Reproduced by kind permission of Specac Ltd., Orpington, Kent, UK.)

provide effective short constant pathlength sampling, typically  $\sim 25 \mu\text{m}$ , and are readily filled and easily cleaned; although, they may require more material than for an equivalent pathlength transmission cell.

Also available for qualitative transmission examination of nonvolatile liquids are microporous polymer film substrates mounted in a standard size sample-holder card; the polymer substrates are usually

either polytetrafluoroethylene (PTFE) or polyethylene into which the liquid is adsorbed. The aperture area of the card in which the substrate is mounted typically has a diameter of 19 mm. For solution samples, where appropriate, the solvent may be allowed to evaporate.

### Pastes, Dispersions, Lattices

Both, liquid and solid sample presentation techniques are used for studying these systems.

Many pastes are most easily directly sampled by internal reflection techniques.

More recent multiple internal reflection accessories, such as the H-ATR (see the section 'Liquids'), have enabled mid-infrared measurements to be made routinely and practically on a wide range of paste-like and latex-like samples and soft waxes. With dispersions, though, there may be a tendency for the solid phase to migrate preferentially to the surface of the internal reflection element. In some circumstances a capillary layer of the material between a pair of transparent infrared windows may suffice. The solute phase of a latex sample is most frequently presented for study as a thin film deposit on a transparent infrared support after elimination (evaporation) of the solvent (see the section 'Films cast from solution').

### Solids

Solid samples not only come in many diverse physical forms (powders, granules, fibers, films, sheet, biological tissue, etc.), but they may also be presented for examination in a wide variety of ways, and analyzed by a range of techniques that include both transmission and reflection methods. In the infrared spectroscopic examination of solids, due attention and consideration must be given to a number of factors.

Although, the infrared absorption characteristics of a solid material may be observed by many sampling techniques, the choice of the sample presentation method will likely be limited by both the study intent and by the sample's physical properties, complexity, and availability. For instance: Can the sample be readily ground to a fine-particle size?; Will the sample thermally degrade if heated?; Does the sample have a composite structure?; Is there a necessity for microsampling or information at high spatial resolution?; Is there a risk of inducing a change in polymorph? The consequences of any sample preparation technique on the sample's physical and chemical characteristics should be carefully considered prior to any examination. Similarly, the influences on the recorded spectra of the presentation method must be fully appreciated.

**Transmission methods** The traditional and most conventional solid sample presentation techniques for mid-infrared spectroscopy are those based on transmission measurements. Also, solids present the greatest choice and consideration in sample presentation methods for transmission measurements, since as discussed above the approach will vary with the nature of the solid and the analytical problem. Solids may be dissolved and examined in solution, or prepared as solid suspensions dispersed in a suitable fluid (the mull method) or a disk of a transparent medium (e.g., KBr). These suspension methods are best suited to crystalline, brittle, or easily ground solids, and are widely applicable to both monomeric organic and inorganic substances. Preparing a thin film from solution or solidification from the melt are methods well suited to examining amorphous materials, such as waxes and soft resins. Organic polymers will often yield self-supporting coherent films when compression molded from the melt, and this is a convenient procedure for many thermoplastic resins. Polymer samples suitable for presentation for transmission measurements may also be prepared by casting a thin film from solution, and in appropriate cases by microtoming sections, cold rolling, or pressing.

In many circumstances thin films or solutions provide the more direct, robust, and reproducible quantitative methods for single component analyses, which will operate over a wide dynamic range and at high sensitivity.

**Solutions** Solids may be examined in solution in transmission cells (see the section 'Liquids'), provided a suitable solvent is available. This can be an effective way of eliminating crystalline lattice effects. However, since no solvent is transparent throughout the entire infrared region, several solvents may be required for complete solute detail, or alternatively an analytically useful difference spectrum may be generated from a single solution, provided solvent-solute interactions are minimal. Solutions offer an important presentation method for quantitative applications, although many of the best solvents are toxic and flammable and must be used with appropriate care, safety, and caution.

**Films cast from solution** Thin films well suited to qualitative analyses, or quantitative measurements if an internal reference band for intensity normalization can be utilized, may often be prepared by casting a thin film from a solution of the sample and evaporating off the solvent. The film may be cast onto an infrared transparent window or onto a suitable support from which it can be readily peeled.

This technique of sample presentation is best suited to volatile solvents, and the sample preparation should be undertaken in a fume-cupboard or other appropriate containment environment. The window, for instance KBr, is placed on a hot-plate, which is then turned on and an appropriate temperature selected. This is normally quite hot to the touch, but not too hot, else the window may crack. Alternatively, the window may be warmed under an infrared lamp. A few drops of the solution are placed on the top surface of the window and gently spread over the entire surface with the tip of the pipette, and the solvent is allowed to evaporate. Successive additions of solution may be used to increase the film thickness. When all the solvent has evaporated and a film of the required thickness has been made, the film and window are allowed to cool to room temperature prior to infrared examination. Persistent solvent residues may need to be removed in a vacuum oven. Spectral contrast will be poor if the variation of the film thickness is large. The film should be uniform in thickness and cover the surface of the window, or be suitably masked, so that no stray-light reaches the infrared detector.

The solvent cast film can prove a particularly useful thin film presentation procedure for many thermoplastic polymers and clearly for solvent-based samples, such as paints, varnishes, and latexes. Though, if the sample crystallizes to any significant extent on evaporation of the solvent, then a highly scattering film may result, which proves unsuitable for transmission studies. AgCl and ZnS are useful supports for films cast from aqueous systems. The casting of thin films from some polyamides (e.g., nylons) dissolved in formic acid onto a glass microscope slide is a well-used example of casting onto a support other than an infrared transmitting window. After evaporation of the formic acid, the sample is water-washed, wiped dry, and then peeled from the glass slide and mounted in an appropriate holder for sample presentation.

Spin coating is a useful method for laying down onto an infrared transparent window a uniform thin layer of a few micrometers thickness of a polymer from a solution. A film can conveniently be cast from a polymer that is soluble in a convenient solvent at a concentration of  $\sim 1\text{--}2\%$ . An example of a spin-coater is shown in **Figure 4**; a clean 13 mm diameter window is attached to the sample stub, onto which several drops of the solution are laid down from a pipette, after which the rotor is spun for a few seconds. Thin films on gold-coated disks suitable for reflection-absorption measurements (see the section 'Thin films on metallic substrates'), may also be prepared by the spin-coating procedure.

**Figure 4** Photograph of a spin-coater for preparing thin films suitable for mid-infrared studies. (The pen is included to give an indication of size.) (Reproduced by kind permission of Cordell Group, Research Engineering, Wilton Centre, Wilton, UK.)

*The mull technique* The basis of this approach is to fill the interstices between the particles of a finely powdered solid with an infrared transparent (or semitransparent) liquid medium. This mixture is then sandwiched into a thin film between a pair of infrared transparent windows. The mull, which should have the consistency of a paste, should be formed in such a manner as to minimize radiation scattering effects.

Ideally, the matrix medium (mulling agent) should have a refractive index matched or close to that of the solid dispersed in it. Also, the solid should be as finely ground as possible, but preferably to a particle size below that of the wavelength being used to study the sample in order to minimize spectral artifacts arising from scatter and anomalous dispersion. Scattering manifests essentially as two effects on the transmission spectrum: a 'sloping background' and absorption band distortion (see **Figure 5**). The spectrum of a mull prepared from a sample that is insufficiently ground will exhibit a gradual decrease in the background transmission from low to high wave numbers, since radiation scatter from particles increases toward shorter wavelengths, and is worse when there is greater mismatch between the refractive index of the dispersant and surrounding medium. In addition, because the refractive index of a sample changes in the vicinity of an absorption band, becoming less than the average to the high wavenumber side of the absorption maximum, and higher than the average to the low wavenumber side, then unsymmetrical scattering loss will be superimposed on the absorption band resulting in the appearance of a distorted band contour. This effect, a consequence of the

**Figure 5** Transmission mid-infrared spectra of liquid paraffin (Nujol<sup>®</sup>) mulls of a phenolic antioxidant for polymers, Irganox 1010 (Ciba-Geigy): (A) poorly ground sample and (B) well-ground sample.

anomalous dispersion in the refractive index, is known as the Christiansen effect (see **Figure 5**).

Mineral oil (liquid paraffin, Nujol<sup>®</sup>) is the most widely used mulling agent. However, this will most likely obscure detail in the C–H stretching ( $3000\text{--}2800\text{ cm}^{-1}$ ) and deformation ( $1500\text{--}1340\text{ cm}^{-1}$ ) regions. In this case, a second mull may need to be prepared, using a halogenated-oil mulling agent such as a perfluorohydrocarbon (Fluorolube<sup>®</sup>) or hexachlorobutadiene. The joint presentations then allow almost total unhindered observation of a sample's mid-infrared absorption bands.

The procedure to prepare a mull is typically to place 10–20 mg of the sample in an agate or mullite mortar, which is then ground to a fine-particle size powder using a vigorous rotary motion of the pestle. A small drop of the mulling agent is then added to the mortar, and rotary motion of the pestle is used to mix the components into a uniform paste. (A common fault is to add initially too much of the mulling agent.) The paste is then transferred to the center of a clean infrared transparent window (e.g., KBr, NaCl, CsI). A second window is then placed on top of the mull and the sandwich squeezed to form a thin film of the mull that is free from bubbles, which often looks translucent. The sandwich may be clamped together in a mull cell.

The mulling technique is not recommended as a general method for presenting samples for quantitative analysis, mainly due to problems of reproducible

grinding; although, if special care is taken, successful semiquantitative analyses may be undertaken. These will necessitate use of a ratioing method to normalize band intensities, or the addition to the mull of an internal standard, although reproducible grinding and uniform mixing of this will require careful attention.

*The alkali-halide disk method* The alkali-halide disk technique is another traditional transmission sample presentation method, in which an intimate mixture of the finely ground solid sample and dry powdered alkali-halide, most commonly KBr, is pressed into a self-supporting disk. Finely powdered dry potassium bromide will coalesce to form a clear disk with high transmission when it is pressed under high pressure in an evacuated die.

The weight ratio of alkali-halide to analyte is large, typically of the order of 200–100:1. As with the mulling technique described in the section 'The mull technique' above, in order to reduce scattering loss and minimize absorption band distortions, the particle size of the sample must be reduced to well below that of the shortest infrared wavelength being used. Infrared spectroscopic-grade quality potassium bromide with a particle size of 100–200 mesh ( $\sim 100\text{ }\mu\text{m}$ ) may be obtained commercially. This should be dried overnight in a vacuum oven at  $\sim 105^\circ\text{C}$ , and then stored in a desiccator. It is important that the KBr is dry in order to eliminate or minimize the amount of adsorbed water in the KBr, which if present will reveal itself in the spectrum as a broad absorption centered  $\sim 3400\text{ cm}^{-1}$  together with a weaker band  $\sim 1640\text{ cm}^{-1}$ . The oven and desiccator should be kept free from other materials to avoid contamination of the KBr. Commercial dies in a range of diameters are available for the preparation of alkali-halide and similar disks, including minidisks (1 mm diameter), although the most commonly used is 13 mm (see **Figure 6**).

Although with experience, preferred local procedures will be developed and become standard practice, these should follow the general principles and the majority of steps outlined below, which is described for the preparation of a 13-mm diameter disk. The manufacturer's recommended procedures should be followed for the operation of the disk-making accessory and the press.

An optimal procedure, recommended by many spectroscopists, requires pregrinding of the sample, prior to mixing of the analyte and KBr to a homogenous mixture, which is subsequently used to make the disk. The pregrinding of the sample is usually achieved by one of the two methods. About 10–20 mg of a sample is ground in a mullite or agate

**Figure 6** Example of alkali-halide disk-making apparatus: (A) photograph of a manually operated hydraulic press for preparing alkali-halide disks and (B) photograph of a range of evacuable pellet dies. (Reproduced by kind permission of Specac Ltd., Orpington, Kent, UK.)

mortar to a fine-particle size, in the manner described for preparing the analyte for a mull in the section 'The mull technique'. An alternative approach, favored by some laboratories, is to use a vibrating agate or steel ball mill. A few milligrams of the sample is placed inside a clean vial together with the balls and ground for a set period of time recommended by the mill manufacturer, typically 30 s. One to three milligrams of the ground powder is then weighed and transferred to a clean mortar, or a clean vial. A weighed amount of dry KBr powder ( $300 \pm 5$  mg) is then added and mixed gently with the analyte to form a homogenous mixture. In a mortar this mixing can be achieved by initially adding  $\sim 15$  mg of the KBr and gently mixing with the pestle, followed by successively adding doubled quantities of the KBr with interleaved mixing. The pestle action should induce good mixing and minimal grinding, since further reduction of the KBr particle size will lead to increased water absorption. If the mixing is to be done in a vial, then the mixing time should consequently be as short as possible. The KBr plus analyte mixture should then be transferred completely to a clean 13-mm die, filling and assembling the apparatus according to the manufacturers' instructions. This die should then be connected to a vacuum system and evacuated for  $\sim 2$  min and placed in a hydraulic press and the pressure applied and increased slowly to the required level. The pressure is usually maintained for between 1 and 5 min, before disconnecting the vacuum, and then slowly releasing the pressure. A pressure corresponding to a dial reading

of  $\sim 10$ – $12$  tons ( $\sim 10\,000$ – $12\,000$  kg) is normally applied to the ram for a 13 mm disk. The disk is then removed from the die and mounted in a KBr disk holder, prior to placing it into the sample holder of the infrared spectrometer.

The KBr disk technique has advantages over the mull presentation method in that KBr exhibits no absorption bands above  $400\text{ cm}^{-1}$  (neglecting any absorbed water or impurities) and is better adapted to micropreparations. However, it may have certain disadvantages. The technique is more prone to introducing changes in sample polymorphism, hydration state, or crystallinity, thereby, tending to make it less reproducible and more unsuitable for studying these effects. In some circumstances ion exchange may occur between the analyte and alkali-halide. Notwithstanding, the presentation method has had widespread applications in the chemical characterization of solids. For less stable solids and polymer samples, wet grinding by adding a drop of ethanol or a solvent to the mortar sometimes proves advantageous; although, appropriate precautions must be taken and the solvent must be allowed to evaporate before adding the KBr. A fine powder may be able to be abraded from a bulk sample with the use of SiC paper or a diamond-dust-studded spatula. Some rubbers, fibers, and other polymer samples may be ground to a useable particle size in a vibrating mill that can be cooled with liquid nitrogen.

Other alkali-halide salts, which are commonly used instead of KBr, are KCl and, for extended low wavenumber observations, CsI, although this is much more hygroscopic and softer. PTFE, may also prove to be a useful matrix medium in some instances. PTFE powder and many of its copolymer powders will cold coalesce at ambient temperature under pressure and the alkali-halide die apparatus is very convenient for preparing analytically useful specimens for infrared transmission presentation. About 300 mg of neat powder is placed in the die and pressure is applied in a manner similar to that described above (without the need of vacuum) to form a translucent PTFE disk. For far-infrared presentation, the matrix disk is frequently made from finely powdered polyethylene.

*Thin films from the melt* Low-melting, thermally stable solids may be presented as thin films prepared by softening or melting a few milligrams of a sample between a pair of infrared transparent plates (windows). The assembly is then squeezed until the softened or molten material has covered the contact surfaces of the plates, and then the assembly is cooled, allowing the material to resolidify. The heating may be accomplished on a gradient temperature hot-plate or by radiation from a heating lamp.

This technique is suitable for amorphous materials, such as waxes, tarry solids, hot melt adhesives, and some low-melting solids. Rubbery materials often have a tendency to retract, since the applied pressure is normally only by hand, and the assembly may need to be clamped. For rubbers it is probably better to prepare a thin film by the melt method described in the section 'Hot compression molded films.' This melt approach is not recommended for materials which will crystallize on solidification, since scatter and molecular orientation effects will lead to both poor spectral contrast and irreproducibility.

*Hot compression molded films* Hot compression molding is one of the most effective and satisfactory means of preparing films from many thermoplastic resin samples for infrared presentation, particularly for quantitative compositional analyses. The polymer must of course be thermally stable at the pressing temperature.

A small laboratory hydraulic press, similar to that shown in **Figure 7**, is convenient for producing presentation samples. Such presses are capable of applying up to 20 tons ( $30 \text{ N m}^{-2}$ ) on the ram. The platens are typically  $\sim 15\text{--}20 \text{ cm} \times 15\text{--}20 \text{ cm}$ . They may be heated electrically to temperatures in excess of  $350^\circ\text{C}$ . Rapid cooling of the platens is provided by cooling water flowing through the platens, which is flushed out by air when at ambient or a cool enough temperature. A control box for programmed heating and cooling cycles may also be incorporated into the press system. The sample may be pressed between a pair of metal plates of the same size as the platens. Polished stainless steel plates, a few millimeters thick, are suitable for the purpose. However, these need to be conditioned to prepare film samples that are optimal for infrared examination. The sample contact surfaces should be grit-blasted (25–30 mesh) and then spray over-coated with a very thin layer of a PTFE, which acts as a mold release agent. The surface roughness introduced should be sufficient to minimize the appearance of an interference fringe pattern in the infrared spectrum recorded from the film sample, while the prepared film is still of uniform thickness such that its average thickness may be accurately determined using a dial-gauge micrometer and used, if necessary, to normalize quantitative band absorbance measurements.

According to the thickness required, which will be dependant on the study purpose and whether a thin film is required for a chemical structure survey or a thick specimen for a quantitative quality assurance application, suitable quantities of the sample may be molded into films with or without the aid of

feeler-gauge blades, or for thicker samples a mold-template may be preferred. For fingerprinting purposes a film thickness of 0.1–0.2 mm is generally used for aliphatic hydrocarbon polymers, whereas for observation of all the peak maxima in the spectrum of an aromatic polyester the thickness may need to be less than  $10 \mu\text{m}$ . The optimum press conditions for a particular material will need to be found empirically, although the compression temperature is likely to be close to the melt temperature of the material. For a thin film,  $<25 \mu\text{m}$ , a few milligrams of the sample are placed between the press plates, and the assembly inserted between the press platens, which have been preheated to the press temperature. The press platens are closed onto the assembly, which is allowed to heat for  $\sim 1 \text{ min}$ , the pressure is then applied for about another minute, the heating is turned off and the water cooling is started following the press manufacturer's instructions. The sample is normally left to cool under pressure, after which the press plates are removed and separated to allow access to the film sample. A safe practice is to handle the press plates with heatproof gloves.

To prevent rubbery samples contracting after pressing, they may be hot pressed and then subsequently examined as a sandwich between two thin sheets of silver chloride. Thin specimens of brittle materials may need to be prepared in a similar manner. Films of high temperature thermoplastics will need to be prepared between aluminum foil, which for thicker specimens can be peeled away to reveal the sample but for thin samples can be dissolved away in caustic or dilute HCl. These should be pressed between uncoated plates, since the PTFE coat should not be heated to temperatures in excess of  $\sim 320^\circ\text{C}$ .

Samples will need to be dry and free from solvent residues before hot pressing, otherwise bubbles may form in the film and lead to the recording of erroneous spectral information. Pressing at too high a temperature or for too long may also give rise to bubbles in the sample, as well as thermal degradation, which if excessive will lead to discoloration. Too low a temperature or insufficient pressure will not cause the sample to fully coalesce, and if, for example, formed from a powder, may give rise to scatter in the spectrum, or, from granules, result in a sample that will separate readily at deformed granule boundaries, or, if formed from stacked layers of film, the sample may delaminate.

For certain analyses it may be desirable to ensure that the hot pressed compression molded film is frozen into an amorphous state. This may be achieved by melting a few milligrams between a pair of thin press plates or aluminum sheet, leaving part of the plates exposed from the press platens. This may be

(A)

(B)

(C)

**Figure 7** Extreme examples of presses for preparing from solids films suitable for mid-infrared examination: (A) hand-operated, hydraulic, heated, molding press for preparing thin films from polymer samples for macro mid-infrared examinations; (B) diamond anvil minicell for solid sample compression and containment, particularly for FT-IR microscopy studies; and (C) schematic of diamond anvil minicell. gripped carefully by a pair of pliers or similar tool held in a thermally insulated gloved hand, the pressure on the platens is then released and the sample-plates sandwich plunged (quenched) into ice-water or Drikold<sup>®</sup> (solid CO<sub>2</sub>)-methanol. At the other

extreme, after the pressure has been applied the electrical heating may simply be turned off and the press with the sample in it kept at pressure and allowed to cool slowly unaided. This annealing will yield a more crystalline morphology in crystalline

and semicrystalline polymers, Although, controlled morphologies are better introduced through the use of programmed temperature cycles, it is possible that metastable crystalline modifications may exist in the freshly pressed film, as occurs for instance with isotactic polybutene-1, which reverts slowly over time from type II (tetragonal crystalline phase) to type I (rhombohedral crystalline domains) with consequent changes in the spectrum, although this is not a particularly common occurrence.

If a prepared film exhibits interference fringes in its infrared spectrum, these may sometimes be suppressed in intensity or eliminated by lightly scouring the film surfaces with wire wool or an abrasive paper.

**Microtomed sections** Sections of appropriate thickness for transmission infrared measurements may be microtomed from continuous solid samples. This presentation method is particularly useful for FT-IR microscopy.

**Reflection methods** Internal reflectance (attenuated reflectance) spectroscopy is a valuable and widely used technique in both qualitative and quantitative examination of solids by mid-infrared spectroscopy. The external reflection technique of reflection-absorption is primarily used for observations on thin absorbing films on reflective substrates; while, although specular reflectance can be of value as a rapid, nondestructive generic fingerprinting tool, its applicability is limited to optically thick samples. Diffuse reflectance mid-infrared spectroscopy can provide a convenient means of examining many finely powdered or highly scattering solid samples. It has particular importance to a wide range of near-infrared (NIR), applications.

**Internal reflection spectroscopy of solids** Mid-infrared internal reflection accessories were developed initially largely for studying the surface layer characteristics of a continuous flat solid sample, e.g., a polymer film; although they may also be used as convenient methods of sample identification, when a surface layer spectrum may be taken as indicative of a sample's bulk characteristics. The sample surface is brought and held under low pressure into optical contact with the clean surface of an internal reflection element. Other common traditional uses have included the direct examination of fibers, foams, and malleable (soft) powders. It has, however, become common practice nowadays, with the sensitivity now available with FT-IR spectroscopy, to use single (or low-number) internal reflection accessories to conveniently and easily record a mid-infrared fingerprint

spectrum from almost any solid sample. An example of such an accessory is shown in Figure 8.

**Thin films on metallic substrates** An analytically useful fingerprint spectrum from a thin film ( $>1000 \text{ \AA}$ ) coated onto a flat reflective metal substrate, e.g., a gold mirror, may be recorded by the reflection-absorption technique. For such film thicknesses, the measurement is relatively straightforward and may be measured in a conventional specular reflectance accessory or in an FT-IR microscope operating in the reflection mode. The infrared radiation beam at near normal angle of incidence makes a double-pass through the film having been reflected back by the substrate. This spectroscopic measurement is often commonly referred to as transreflectance. It must be remembered that superimposed on the essentially double-pathlength transmission spectrum will be a weaker specular reflectance spectrum which will mostly distort the stronger absorption bands, and in some circumstances cause band inversion.

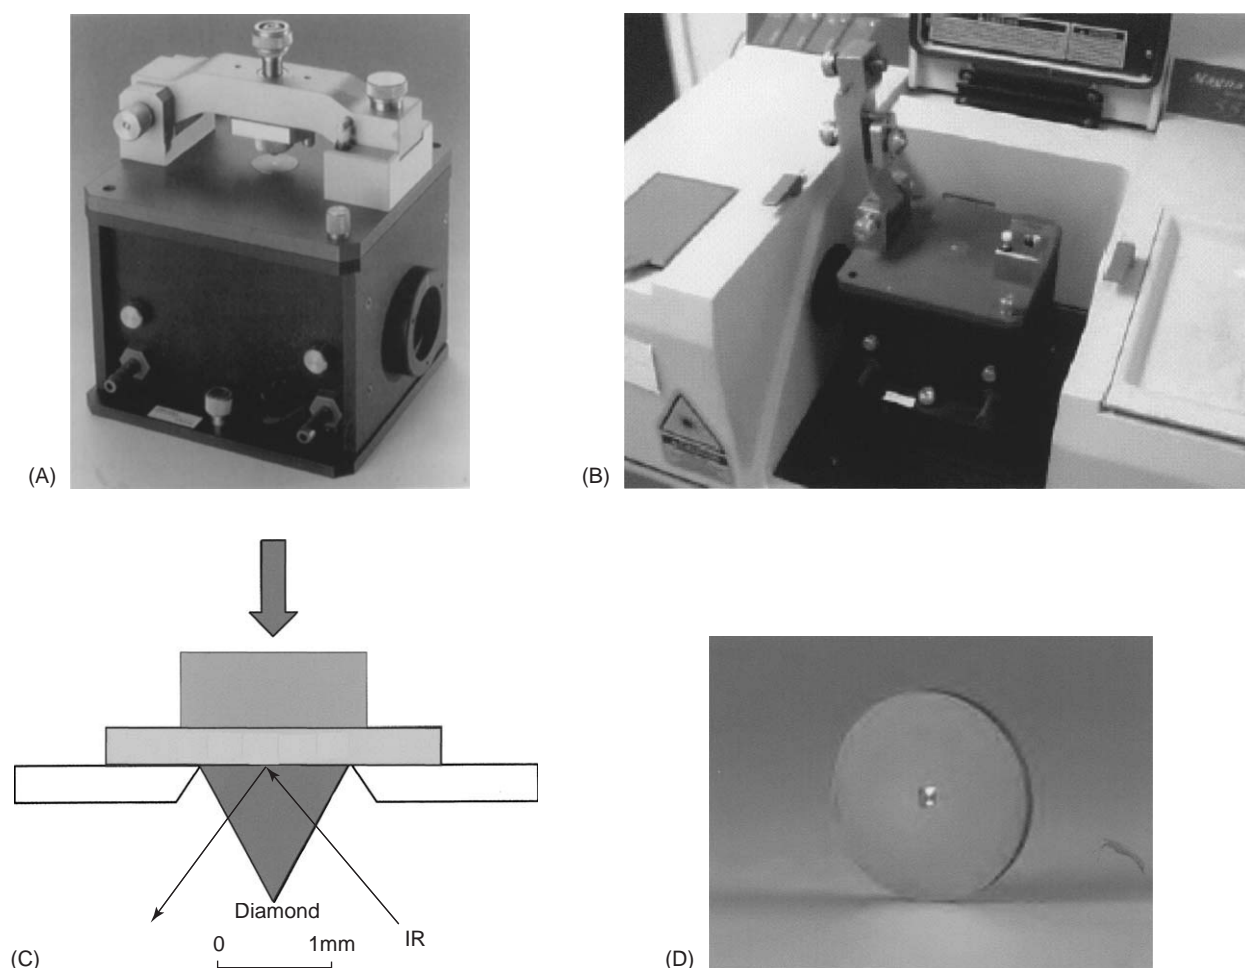

For much thinner films, such as monolayers, the more specialized technique of grazing-angle incidence reflection-absorption is used.

**Specular reflectance** Pure specular reflection spectra may be recorded directly from the surfaces of flat, nonscattering, optically thick (opaque) samples from which the absorption index spectrum may be extracted by application of the Kramers-Kronig algorithm. This is sometimes a useful approach for generically fingerprinting intractable or heavily filled polymer samples. An example is shown in Figure 9.

**Diffuse reflection** Diffuse reflection is a very convenient and useful method for examining by mid-infrared FT-IR spectroscopy highly scattering solids using minimal sample preparation. The diffusely scattered radiation is collected by some high-efficiency collection optics. The spectral contrast depends strongly on the physical and optical properties of the sample. In the mid-infrared region it is primarily a qualitative tool, although sometimes used for low precision semiquantitative measurements. Diffuse reflection is a commonly used sampling technique with NIR spectroscopy.

The majority of samples for mid-infrared investigations are presented as finely divided powders dispersed in an excess of a dry powdered nonabsorbing matrix, commonly KCl. This ensures that superimposed interferences from specular (front-surface) reflections are minimized in the recorded diffuse reflection spectrum. A useful approach for sampling intractable, composite, or gross objects is to abrade a fine powder from the article's surface with some SiC

**Figure 8** Single-reflection ATR accessory: (A) photograph of Golden-Gate™ single-reflection ATR accessory; (B) photograph of Golden Gate™ accessory sited in the sample compartment of an FT-IR spectrometer; the pressure bridge is raised; (C) schematic of a single-reflection ATR system; and (D) photograph of diamond ATR element bonded into its tungsten carbide mount in the accessory top-plate. or diamond powder abrasive paper. The abraded powder may then be examined *in situ* on the abrasive paper or removed and dispersed in KCl powder. Diffuse reflectance can also be a particularly convenient method for examining directly foamed materials.

**Other solid sampling techniques** While in an article such as this, it is not possible to cover all mid-infrared sampling techniques; two other methods that have been used significantly in analytical spectroscopy applications are photoacoustic spectroscopy and emission spectroscopy.

**Photoacoustic spectroscopy** Mid-infrared spectra may be recorded by photoacoustic FT-IR spectroscopy from solids having a wide range of physical forms with minimal requirement for any sample preparation.

Photoacoustic spectroscopy provides a convenient qualitative sampling procedure for recording an absorbance spectrum from a wide range of solid materials regardless of their morphology. Essentially the only requirement is that the sample be made to fit into the photoacoustic cell sample holder, although sample form will affect spectral contrast and intensity. Consequently quantitative studies are usually restricted to measurements of a band ratio from a pair of weak to medium intensity bands.

**Emission spectroscopy** An alternative method of measuring the infrared spectrum of a thin film on a metallic substrate is to heat the sample and record its emission spectrum. A temperature of 50–100°C should suffice. This can be particularly useful for nonflat samples such as coatings on drinks or food cans; generic identification of such coatings is

probably now, however, more readily undertaken by transmittance under an FT-IR microscope.

## Trends in Sample Preparation

In the analytical laboratory, FT-IR spectrometers are now dominant, if not the almost exclusive mid-infrared tool. Many are also interfaced with FT-IR microscopes that enable high signal-to-noise ratio spectra to be recorded routinely from regions of samples with diameters as low as 20  $\mu\text{m}$ , in some cases 10  $\mu\text{m}$ . There is now a much greater emphasis on sampling techniques appropriate to biological and biomedical samples.

With the growth of FT-IR instrumentation in analytical laboratories throughout the 1980s and 1990s, there was an accompanying introduction and acceptance of many novel sample presentation procedures for mid-infrared spectroscopy. These included photoacoustic and many adaptations of the internal reflection spectroscopy technique, such as the H-ATR. In addition, the rarely used sampling technique of diffuse reflectance became routinely practicable in the mid-infrared region. As a consequence, there was a significant shift from the use of classical transmission measurements utilizing alkali-halide disks, mulls, and thin pathlength liquid cells, to less protracted preparation procedures, particularly

for qualitative purposes. Also, in the 1990s and early 2000s there were significant developments that made Raman spectroscopy available as a convenient, comparable cost, increased sensitivity technique, which with its much lower demands for sample preparation have meant that in niche areas, such as pharmaceutical polymorphic studies and art and archaeology forensics, its use has tended to not only complement but also supplant some mid-infrared applications.

Lately, the single-reflection mid-infrared ATR accessories have proven to be a very attractive tool within an industrial environment; they provide a simple to use means of quickly recording a mid-infrared spectrum from almost any solid material. With the acceptance of these and the increased number of installations of FT-IR microscope systems, there has been a general decline in the use of the diffuse reflection and photoacoustic techniques in the mid-infrared region, and emission measurements are now very rarely used.

Imaging has also become an important interrogation tool, and there is increasing use of FT-IR spectrometers, particularly FT-IR microscope systems, to generate spectroscopic images from samples. Consequently, there is a growing emphasis on methods of sample preparation that optimize specimens for such interrogations.

## Introduction

Since the 1970s, near-infrared (NIR) spectroscopy has been applied as a qualitative and quantitative analytical tool in the industrial fields of agriculture, food, chemical and textile production, and pharmaceuticals. The technique is capable of making rapid, nondestructive multicomponent analyses of organic materials in a complex background matrix. In situations where inorganic materials are dissolved in polar solvents an indirect NIR measurement can be obtained. If the concentration of an analyte exceeds 0.1% then it is likely that an acceptable analytical error will be achieved. NIR spectroscopy is essentially an applied instrumental technique not often used in a pure research context, unlike the related mid-infrared (mid-IR) spectroscopy, the spectra from which can be interpreted to identify specific organic bond pairs, e.g., CO, OH, NH. This article discusses the physical theory underpinning the use of NIR, NIR calibration methodology, and types of instrumentation. Examples are given of the application of the technique in the industrial contexts noted above.

## NIR Theory – Molecular Spectroscopy

Two main areas of physical theory are relevant to the application and understanding of NIR: first, the chemical principles derived from quantum physics and molecular spectroscopy, and, second, the physical principles used to relate the spectra to transmission or diffuse reflectance of electromagnetic energy.

Mid-IR and NIR spectra are generated via appropriate instrumentation by electromagnetic energy absorption between 400 and 12 500 nm. Subsets of the wavelength range are employed by instruments with detectors and energy sources appropriate for obtaining spectra in their particular range. The mid-IR range is about 2500–25 000 nm, the NIR range about 1100–2500 nm, and the visible range about 400–800 nm. In the mid-IR range it is usual to refer to wavenumber or frequency in  $\text{cm}^{-1}$  according to the formula wave number ( $\text{cm}^{-1}$ ) =  $10^7/\text{wavelength (nm)}$ .

The mid-IR region provides fundamental absorption data, whereby for a specific bond pair the energy transfer from one level to another occurs at a unique frequency. It is for this reason that the mid-IR region has been used to analyze the bond pairs in organic molecules. It is the  $3600\text{--}1200\text{ cm}^{-1}$  region that gives rise to the overtones in the NIR part of the spectrum. The NIR region thus consists of overtones and combination bands that result in broad and/or overlapping absorption peaks. It is for this reason that NIR spectroscopy employs more statistical, mathematical approaches to the analysis of organic constituents, compared with the approaches used in mid-IR spectroscopy.

Thus, the two regions, although instrumentally and chemometrically distinct, are theoretically parts of the same vibrational and rotational spectroscopic model. Figure 1 illustrates the basic models for energy absorption by covalently bonded atoms of dissimilar mass. A dipole moment (produced when atoms of dissimilar mass are bonded) is a basic condition for absorption to occur. The H–H bond, for example, does not produce mid-IR or NIR absorbance. When molecules are subjected to an

## Introduction

Since the 1970s, near-infrared (NIR) spectroscopy has been applied as a qualitative and quantitative analytical tool in the industrial fields of agriculture, food, chemical and textile production, and pharmaceuticals. The technique is capable of making rapid, nondestructive multicomponent analyses of organic materials in a complex background matrix. In situations where inorganic materials are dissolved in polar solvents an indirect NIR measurement can be obtained. If the concentration of an analyte exceeds 0.1% then it is likely that an acceptable analytical error will be achieved. NIR spectroscopy is essentially an applied instrumental technique not often used in a pure research context, unlike the related mid-infrared (mid-IR) spectroscopy, the spectra from which can be interpreted to identify specific organic bond pairs, e.g., CO, OH, NH. This article discusses the physical theory underpinning the use of NIR, NIR calibration methodology, and types of instrumentation. Examples are given of the application of the technique in the industrial contexts noted above.

## NIR Theory – Molecular Spectroscopy

Two main areas of physical theory are relevant to the application and understanding of NIR: first, the chemical principles derived from quantum physics and molecular spectroscopy, and, second, the physical principles used to relate the spectra to transmission or diffuse reflectance of electromagnetic energy.

Mid-IR and NIR spectra are generated via appropriate instrumentation by electromagnetic energy absorption between 400 and 12 500 nm. Subsets of the wavelength range are employed by instruments with detectors and energy sources appropriate for obtaining spectra in their particular range. The mid-IR range is about 2500–25 000 nm, the NIR range about 1100–2500 nm, and the visible range about 400–800 nm. In the mid-IR range it is usual to refer to wavenumber or frequency in  $\text{cm}^{-1}$  according to the formula wave number ( $\text{cm}^{-1}$ ) =  $10^7/\text{wavelength (nm)}$ .

The mid-IR region provides fundamental absorption data, whereby for a specific bond pair the energy transfer from one level to another occurs at a unique frequency. It is for this reason that the mid-IR region has been used to analyze the bond pairs in organic molecules. It is the  $3600\text{--}1200\text{ cm}^{-1}$  region that gives rise to the overtones in the NIR part of the spectrum. The NIR region thus consists of overtones and combination bands that result in broad and/or overlapping absorption peaks. It is for this reason that NIR spectroscopy employs more statistical, mathematical approaches to the analysis of organic constituents, compared with the approaches used in mid-IR spectroscopy.

Thus, the two regions, although instrumentally and chemometrically distinct, are theoretically parts of the same vibrational and rotational spectroscopic model. Figure 1 illustrates the basic models for energy absorption by covalently bonded atoms of dissimilar mass. A dipole moment (produced when atoms of dissimilar mass are bonded) is a basic condition for absorption to occur. The H–H bond, for example, does not produce mid-IR or NIR absorbance. When molecules are subjected to an

**Figure 1** Hooke's law and Morse curves as functions of energy and interatomic distance.

external energy source they acquire the potential for energy changes and the amount of energy that can be imparted from a source is dependent upon the wavelength, according to the formula:

$$E = hc\bar{\nu}$$

where  $E$  is the energy,  $h$  is Planck's constant ( $6.626 \times 10^{-34}$  J s),  $c$  is the speed of light, and  $\bar{\nu}$  is the wave number in  $\text{cm}^{-1}$ .

When organic molecules absorb energy from an external source, e.g., a tungsten or halogen (while tight) lamp, some molecules will move from the ground state ( $v = 0$ ) to the next energy level ( $v = 1$ ) (see **Figure 1**). The combined vibrational and rotational energy changes involved in the energy level change constitute the absorption process.

**Figure 1** illustrates the simplest theoretical treatment for the energy absorption behavior of covalent bonds. Hooke's law curve corresponds to bonds vibrating in simple harmonic motion. In practice, covalent bond vibrations are anharmonic and follow the potential energies depicted in the Morse curve, also illustrated in **Figure 1**. It is this phenomenon of anharmonicity that allows the overtones or harmonics to occur in the NIR region. Thus, the frequencies of the overtones are slightly less than whole number

multiples of the fundamental frequency. Greater amounts of energy are required to displace molecules to higher overtones and the numbers of molecules displaced is in inverse proportion to the overtone number. Transitions occur most frequently from the ground state ( $v = 0$ , see **Figure 1**) to the first level, and are increasingly infrequent for the higher levels. Consequently, higher overtone absorptions are much weaker than the fundamental.

Combination bands are also encountered in NIR spectra. These result from energy transitions involving two or more different vibrational modes for the same functional group. For example,  $\text{CH}_2$  groups have two symmetrical vibrational modes, a symmetric stretching mode, and a corresponding in-plane bending, or scissoring. The combination band resulting from these two vibrational modes is seen at 2320 nm. A final factor that has been identified as complicating NIR spectra even further is that of Fermi resonance. In this condition, unlike sets of bonds, e.g., the O-C-O bending mode and the symmetrical C-O stretching mode, occur at approximately the same frequency and a repulsion occurs. One type of bond energy level is lowered and the other type gains energy. In the case of carbon dioxide this results in bands at 1388 and 1286  $\text{cm}^{-1}$  instead of one strong and one weak line at 1340 and 1330  $\text{cm}^{-1}$ , respectively. Although relatively obvious in the mid-IR region, Fermi resonance phenomena are usually hidden beneath the broad overlapping peaks in the NIR.

Although NIR absorbance peaks are generally broad, spectral assignment is possible. A number of authors have discussed bond assignment in the NIR region and tables and lists of assignments of particular bonds and vibrational modes have been published.

### Transmission and Diffuse Reflectance

When NIR radiation is passed through a non-scattering organic medium, the intensity of absorption can be described in terms of transmittance,  $T$ :

$$T = I/I_0$$

where  $I$  is the intensity of the emergent radiation and  $I_0$  is the incident energy. For absorption spectra,  $I$  can be expressed in terms of the Beer-Lambert relationship:

$$\log_{10}(I_0/I) = \log_{10}(1/T) = kcl = A$$

where  $A$  is the absorbance,  $k$  is the molar absorptivity,  $c$  is the concentration of the absorbing molecular species, and  $l$  is the pathlength of energy

through the sample. For a fixed pathlength the absorbance is thus directly proportional to the concentration of the absorbing species.

In the case of samples that produce scatter in transmission or diffuse reflectance spectra, a number of factors corrupt the linearity of the Beer–Lambert absorbance concentration relationship. Sample scattering of radiation results in an alteration of the proportion of absorbed and reflected radiation so that pathlength becomes another unknown in the Beer–Lambert relationship. Particle size, particle shape, crystalline form, bulk, density, and the nature of the pore space (filled with air, water, or oil) are all variables that dictate the effective pathlength of the radiation. Sample surfaces also reflect specular energy that has not interacted with molecular structures. This form of energy has an overall effect on spectra, contributing primarily to the curvilinearity of the spectral baseline.

A number of attempts have been made to describe both theoretically and practically diffuse reflectance and scattering functions to enable a linear relationship to be established between absorbance ( $A$ ), expressed as  $\log_{10}(1/R)$  where  $R$  is the reflectance, and molecular concentration. Perhaps the commonest relationship encountered is that ascribed to Kubelka and Munk, who established nine assumptions and 16 variables. These can be simplified to the Kubelka–Munk function, namely:

$$\frac{(1 - R_{\infty})^2}{2R_{\infty}} = \frac{K}{S} = \frac{kc}{S}$$

where  $R_{\infty}$  is the reflectance for a sample of effectively infinite depth,  $K$  is a constant proportional to the  $kc$  term in the Beer–Lambert relationship,  $S$  is a scattering coefficient usually taken as  $\delta^{-1}$  where  $\delta$  is the diameter of the particles in a densely packed scattering medium,  $k$  is the molar absorptivity, and  $c$  is the concentration of the absorbing analyte.

## NIR Calibration Development

The most important first step in the practical application of NIR is appropriate sample selection. To take advantage of the potential rapidity and accuracy of analysis that NIR spectroscopy can offer, the NIR instrument must be calibrated against an acceptable, accurate, and reproducible laboratory method for the analyte or analytes of interest. The selection of a sample set for NIR scanning and laboratory analysis should be, as far as practically possible, representative of the material that the calibration will encounter when it is used to predict the targeted analyte or analytes. Another critical aspect of NIR analysis

is appropriate and repeatable sample presentation. Instrument manufacturers provide a plethora of sampling devices that attempt to optimize presentation criteria for specific sample types.

One approach to establishing a calibration sample set is to scan a large number of samples that represent the potential population to be predicted and to submit the spectra to an analysis that establishes which combination of samples shows the largest spectral variability overall. This smaller subset of samples can then be analyzed by the laboratory method. In practice, it will seldom be possible to establish calibrations that will optimally predict all future samples. It is therefore helpful to include new samples in the calibration that are spectrally different from the original calibration set. The standard error of calibration (SEC) is used as an indication of the efficacy of a calibration.

It is equally important that a calibration is tested against a set of samples different from those of the calibration set. They should ideally be separately collected but they must embody the chemical and physical features encompassed by the calibration set. It is the standard error of prediction or performance (SEP), which defines the success of a calibration. It is important, however, to relate the SEP to the overall range of the analyte in question.

The factors listed below are commonly responsible for increasing the prediction error:

- faulty laboratory analysis,
- sample heterogeneity,
- lack of repeatability in the packing and presentation of the sample,
- instrumental malfunction.

The standard deviation for the residuals is due to differences between the laboratory analytical values and the NIR predicted values for samples in the calibration set (SEC) or in a test set (SEP).

## Mathematical Data Treatment

Although the theoretical models noted above attempt to satisfy well-established physical principles, in practice most NIR workers start the calibration equation development process with the orthodox  $\log_{10} 1/R$  or  $\log_{10} 1/T$  spectra. Although calibrations have been generated using the ‘draw’ log reciprocal data, it has been found in most cases that some form or forms of mathematical data treatment prior to regression analysis improves a calibration substantially.

Mathematical approaches that have been employed to obviate instrumental noise and other

physical effects in favor of chemical features in NIR spectra include:

**Smoothing functions** The simplest smoothing function employed is to average the absorbance ( $\log 1/R$  or  $\log 1/T$ ) values over a segment of the spectrum. Many other smoothing algorithms are available to smooth noisy spectra and reduce the numbers of wavelengths in spectra. It should be noted, however, that a high signal-to-noise ratio is characteristic of NIR spectra and smoothing algorithms are primarily used as an initial data reduction step.

**Derivative functions** Derivative functions (strictly termed differencing) provide a plot of the rate of change of the slope in the spectrum. The average slope is defined over a spectral segment that is followed by the omission of several wavelengths (a gap). The gap may be zero. The process is repeated along the spectrum to its final wavelength. This finite difference technique is usually combined with a smoothing algorithm. The size of the gap and segment may be varied. This technique has the effect of removing parallel baseline shift due to particle size differences in the samples, but it retains slope differences between spectra, and thus retains the basic peak height molecular species concentration relationship. Derivatized spectra contain lobes and valleys and inflected peaks and are therefore difficult to interpret. Up to four orders of derivative have been employed with NIR spectra. Trial and error and experience with gap and segment sizes provide optimal solutions for calibrations and predictions.

**Multiplicative scatter correction (MSC)** The model is based partly upon theoretical considerations of radiation scatter and partly upon empirical observations of spectra.

If  $x_1, x_2, \dots, x_k$  are the absorbance values of a sample and  $\bar{x}_1, \bar{x}_2, \dots, \bar{x}_k$  are the average absorbance values for the set of samples. The regression model used is:

$$x_k = a + b\bar{x}_k + e_k$$

The coefficients  $a$  and  $b$  are estimated by least squares over the wavelength range and the scatter-corrected spectrum is obtained by subtracting  $a$  and dividing by  $b$ , i.e.,

$$x_{k\text{new}} = (x_{k\text{old}} - a)/b$$

$e$  is a term accounting for 'error' caused by, for example, random measurement noise. MSC also requires a linearity transform to ensure a linear relationship between absorbance values at wavelengths absorbing for the analyte of interest.

**Standard normal variate (SNV) and detrending** For a given set of similar samples the reflectance spectra will vary in their slope and curvilinearity according to the particle size distribution between samples, differences in crystallinity, and differences in the chemically nonspecific scatter at the sample surfaces.

The SNV function for a 700 wavelength spectrum may be expressed as:

$$\text{SNV}_n = y_n - \bar{y} \left[ \sum_{i=1}^n (y_i - \bar{y})^2 \right]^{-1/2} \quad (n-1)$$

$$n = 1, \dots, 700$$

where  $\text{SNV}_n$  ( $n = 1, \dots, 700$ ) are the individual SNV terms for each of the 700 wavelengths,  $y_n$  are the 700  $\log 1/R$  values, and  $\bar{y}$  is the mean of the 700  $\log 1/R$  values.

A dominant feature of NIR diffuse reflectance spectra is the increase in absorbance values from 1100 to 2500 nm. This trend is curvilinear for densely packed samples. A second-degree polynomial function has proved to be an adequate model to linearize the spectral baseline.

The list of NIR spectral transformations is not exhaustive but it exemplifies the physical features that are perceived to interfere with the chemical absorbance features and the approaches used to overcome the perceived interference in diffuse reflectance NIR spectroscopy.

None of the above approaches optimizes the relationship between NIR absorbances and analyte for a range of sample types. Derivative transformations have been found to be generally useful when stepwise multiple linear regression (SMLR) techniques are used. When multidimensional statistics are employed, e.g., partial least-squares (PLS), principal component regression (PCR), or neural nets, it has been observed in some cases that the untransformed  $\log 1/R$  data can perform just as well in correlation coefficient and error terms as in any kind of transformation. It is considered that in some cases physical manifestations of the sample contained in the spectra provide valid and useful discriminant data.

## Fourier and Wavelet Transforms

In the past, the large amount of spectral data generated by NIR instruments challenged the ability of computers to provide computations within a reasonable time frame. Mathematical techniques, therefore, which offered a reduction of the raw data, but with minimum loss of information, were often employed. The decomposition of 1000 spectral data points to 100 Fourier transform coefficients provides a great saving in computational time with very little loss of

spectral information. Large memory computers have meant, however, that NIR workers can derive functional calibrations or discriminant functions using all the spectral data. With the advent of spectral imaging datasets, and very large sample databases, the need has reemerged for efficient data reduction techniques. One of the most recent, and promising techniques is wavelet transformation. This technique employs various wave functions that can be combined to represent a spectrum. Wavelet transforms have not been used widely so far, but there is hope that they may provide a powerful way of data reduction without loss.

### Developing the Regression Equation

Until recently, it was most common to use SMLR to develop a calibration model. A condition for the use of the technique is that the relationship between absorbance expressed as  $\log_{10} 1/R$  or  $\log_{10} 1/T$  and the laboratory measurement should be very close to linear. The specular reflectance and particle size effects seen in spectra discussed below also affect the optimal reduction of the SEC and SEP.

When the laboratory value is plotted against the NIR predicted value for the calibration sample set it may well be noted that some points lie well away from the computed regression line. This will, of course, reduce the correlation between laboratory and NIR data and increase the SEC or SEP. These samples may be outliers. The statistic  $h_i$  describes the 'leverage' or effect of an individual sample upon a regression. If a particular value of  $h_i$  is exceeded this may be used to determine an outlier sample. Evaluation criteria for selecting outliers, however, are somewhat subjective so there is a requirement for expertise in multivariate methods to make outlier selection effective.

Intercorrelation (or multicollinearity) phenomena also reduce the effectiveness of a calibration. First, there can be intercorrelation between the constituents in the samples. For example, water and fat in some meats are negatively correlated and it is possible to obtain the same calibration wavelengths for both components although the two components do not absorb in the same band.

Particle size differences between samples cause all calibration coefficients to change because of the baseline shift of the spectra. Furthermore, adjacent wavelengths are also highly correlated, so it is difficult for the SMLR algorithm to 'focus' on a single combination of wavelengths that will optimize the terms in the calibration. There are also correlations between areas in the spectrum that represent overtones of the same covalent bond.

It is often suggested that slope and bias corrections should be made to computed regression models, i.e., an adjustment be made to the regression line so that it can be extrapolated through the zero laboratory/NIR prediction values (bias or intercept). This procedure will also adjust the slope term in the equation. The most recent view of this technique is that it should be used with utmost caution, in that if such adjustments are apparently required to improve the statistical results then it probably indicates that the original model requires improvement or that laboratory or NIR measurements are at fault.

### Multidimensional Regression Techniques

There are a number of multidimensional, multivariate techniques that are capable of overcoming many of the effects that corrupt calibrations, without necessarily using data pretransformations. These techniques also involve wavelength data compression, resulting in a decrease of computational time. Equations are also derived from functions of the whole spectrum. PLS and PCR are the most commonly used of these techniques. Both techniques derive linear functions from the wavelength data (latent variables in PLS, principal components in PCR). Typically, a few of the functions in relationship to the sample number will provide sufficient data to generate coefficients for good calibrations equations.

In PCR, the components are derived by extracting the maximum amount of residual variation from the spectral data. Each principle component is orthogonal to the next (they have 0 correlation). In this way the wavelength intercorrelation problem noted above is alleviated. PLS functions are derived by interrelating the laboratory value variability and the NIR spectral variability and latent variables have low intercorrelation. Although a number of writers point to relative advantages for these techniques, in practice, used properly, they provide similar solutions. Fourier transform techniques are also used for calibration. Once again the wavelengths are compressed into a relatively few (Fourier) coefficients. In common with PLS and PCR, the adjacent Fourier functions (coefficients) have a low intercorrelation.

The three techniques of multidimensional calibration noted above also generate functions that are valuable for the chemical and physical interpretation of spectra.

Principle components regression, for instance, generates 'loadings' for each principal component (PC) that may be plotted against wavelength, to illustrate the importance of specific wavelength regions to the regression analysis. The peaks and troughs of the plot correspond to high positive or

low negative loadings on the ordinate axis and are indicative of the degree of influence that the wavelength regions, encompassed by the peaks or troughs, have on the final model. Since the loadings are calculated from spectral variation in the whole sample set, the loadings against wavelength plot reflects spectral features in the dataset. **Figure 2** shows the loadings against wavelength plot for the second PC derived from a set of orange juice samples. In this plot, the peak at 2100 nm is homologous with a peak in the orange juice spectra at 2100 nm (see **Figure 3**), which in turn is a characteristic peak in the spectrum of sucrose, and sucrose is a major varying constituent of the orange juice samples from which the PC was derived. **Figure 3** illustrates an orange juice spectrum. In **Figure 4**, the first PC loadings are plotted against wavelength for the orange juice reflectance data referred to above. In this case, the plot shows a weak 'smoothed' orange juice spectrum (*cf.* **Figure 3**). This

represents a spectral pattern that is generated by specular (mirror-like, no interaction with molecular bonds) reflection and particle size differences between samples. **Figure 5** shows a series of leaf tea reflectance spectra where the spectra are very similar in shape but the spectra are spaced up and down the ordinate axis. This is a typical spectral response to samples with particle size differences.

Fourier analysis offers the process of self-deconvolution that is capable of resolving underlying peaks from broad overlapping bands. Fourier self-deconvolution has the advantage over derivatized spectra that there is no shift or averaging effect and the self-deconvoluted spectrum is directly comparable with the log/reciprocal wavelength scale.

Two other techniques of calibration equation computation have recently been used by NIR workers, locally weighted regression (LWR) and artificial neural nets.

**Figure 2** Second principal component loadings versus wavelength plot of a set of 25 components used for canonical variates analysis of orange juice NIR reflectance spectra.

**Figure 3** log 1/R spectrum of orange juice dried onto a glass fiber disk.

**Figure 4** First principal component loadings versus wavelength plot for a set of orange juice reflectance spectra.

**Figure 5**  $\log 1/R$  spectra of tea leaf samples showing the 'stacking' of similarity shaped spectra along the ordinate axis.

LWR has been recommended to counteract the common inherent nonlinearity existing between laboratory values and the spectral absorbances. Essentially, segments of the NIR versus laboratory value regression computed are used to give a much better approximation to linearity than a regression line model for the whole dataset.

### Neural Networks

Neural networks have been used, most effectively, as a way of establishing robust NIR calibrations. It is the calibration method of choice for a whole cereal grain, transmission instrument, which is being used worldwide for many of the analyses required for estimating grain quality. An artificial neural network program performs many iterations in order to establish the optimum solution required from large, complex datasets.

### Discriminant Analysis

NIR instruments may not only be calibrated for quantitative analysis, but they may also be 'trained' for qualitative purposes. This process is usually termed discriminant analysis. The criteria noted previously for establishing quantitative calibrations with minimum prediction error are equally applicable to discriminant calibration sets.

Spectral matching algorithms are also employed using multidimensional mathematics. Such techniques are often used in quality assurance programs where a spectrum of a known material is compared with incoming raw materials to check its purity or authenticity. For example, samples of orange juice concentrate were collected to represent the types available from two countries. In addition, samples that were known to be adulterated were obtained from one of the countries. All other samples were

characterized as authentic. The question asked was 'Can NIR spectra be used to discriminate between the three categories of juice concentrate?' That is, country A, country B (authentic), and country B (adulterated).

The technique chosen to perform the analysis was canonical variates analysis. Briefly, the method abstracts functions from combinations of PCs. It has been found with large sample sets ( $\geq 100$  or more) that up to 25 PCs give optimal predictive ability. It is unwieldy to select the predictively important analytes from 25 PC dimensions. For this reason the PC-derived canonical varieties are computed wherein the dimensions available are one less than the number of ascribed characteristics or groups. In the example noted above, therefore, the two CVs describe the 25 PC dimensions, since there are three groups in the analysis. In this example, a calibration discriminant analysis was calculated using 71 samples, and 23 prediction samples were used to test the calibration. **Figure 6** illustrates the two-dimensional CVs' calibration and prediction.

One problem that is evident from this analysis is that samples that lie outside the defined circles (95% of the samples sample points should lie within the group circles providing each group has the same variance), may (1) belong to one of the defined groups or (2) belong to a population not defined in the calibration. At present no satisfactory method exists to make an objective decision about such 'outlier' samples. One approach to help with this problem is to employ cluster analysis techniques. In this case sample spectra are allotted to specific groups in a hierarchical fashion, beginning with a division of the sample set into two groups, then four, and so on. This type of analysis requires decisions to be made about appropriate distance and similarity functions, which are required to perform the computations. There are many such functions and only experience of their use leads to valid analysis and samples that may be truly outside the group populations will at some level of the analysis be included in a group.

### A Nonregression-Based Technique

Comparison analysis using restructured near-infrared and constituent data (CARNAC) can be used to provide quantitative or discriminant analysis for large databases. In the current version of the technique, CARNAC-D, wavelet transforms are used to reduce the spectral information, and then the spectrum of the sample requiring a particular analyte measurement or discriminant comparison (transformed in the same way) is compared with the 'calibration' database. The sample giving the closest

**Figure 6** Canonical variates calibration and prediction sample plot of NIR diffuse reflectance spectra characterized as: ▲, △, country A; ●, ○ country B (authentic); and ■, □, country B (adulterated). Solid symbols, calibration samples; hollow symbols, prediction samples.

match gives the solution to the required analyte or discriminant identification.

## Types of NIR Instrumentation

Until the late 1980s there were only two basic types of NIR instrument, those employing discrete wavelength filters and wavelength scanning instruments using holographic gratings. Both types employ high-intensity white light sources and one or two types of detector depending upon the wavelength range being used. For the NIR region (1100–2500 nm) a lead sulfide detector provides appropriate sensitivity and in the higher-energy visible/far visible region from 400 to 1100 nm less sensitive silicon detectors are used.

Detector geometry is important to optimize the collection of diffuse reflectance energy in favor of specular reflectance energy that contains no chemical absorbance information. Two approaches are commonly used. One uses an integrating sphere that provides a double-beamlike instrument, whereby the arrangement of the detectors within the reflective sphere enables a reference and a sample beam to be employed. The reference spectrum is subtracted from

each sample spectrum obviating the inclusion of purely instrumental contributions to the sample spectrum. Single-beam instruments, using a detector array set to 45° to the sample surface, must have a reference material to scan, the spectrum of which is subtracted from the sample scan. The full-wavelength scanning instruments are more expensive than filter instruments and are in general used for calibration development and applied research.

In the late 1980s and into the new millennium instrumental approaches to the NIR region have increased substantially and some of these new approaches are noted briefly below.

### Calibration Transfer

NIR instruments of all kinds differ in their optical and operational properties. Instruments of the same kind and make have small differences, but these produce differences in spectra that are sufficient to erode the accuracy of a calibration if it is transformed from one instrument to another. There has been, and there continues to be, an interest in ways of transforming calibrations, such that, when they are

transferred from one instrument to another they retain their predictive accuracy in the new instrument.

### **Transmission through Solids**

Using the higher-energy visible region, instruments have been made to provide transmission spectra of solid samples that have been satisfactorily calibrated for kernel hardness of gain, meat components, and tenderness of peas, for example.

### **Photodiode Array Instruments**

Photodiode array (PDA) type of instrument is solid state (no moving parts) and because of the electronic switching of the diodes providing the NIR illumination, it is very rapid scanning, compared with other instrument types. Such a construction lends itself to miniaturization, and the result is physically robust, enabling it to be used in many situations where other instrument types could not be used, including situations where a hand-held analyzer is required. At present the wavelength range is limited between 500 and 1100 nm (other instruments can provide wavelengths up to 2400 nm). The spectra from a PDA instrument also tend to be noisier than spectra from other instruments. Currently, this type of NIR analyzer is being used as an integral measurement system in a cereal combine harvester. It is also being used experimentally to estimate quality parameters of whole fruit on the tree. The uses for this NIR technology are increasing rapidly.

### **NIR Image Analysis**

Developments are currently taking place in using the visible and NIR region for video imaging purposes. Experiments have been carried out to image meat surfaces and the textural appearance of bread crumbs.

A leading pharmaceutical manufacturer has developed an NIR-based image analysis technique to image the ingredients of capsules and tablets to check there even distribution in a formulated product.

Diffuse reflected NIR radiation from the surface of the sample is collected by a series of imaging optics and passes through an NIR tunable filter prior to forming an image on an IR focal plane array detector. The filter is continuously stepped through a predetermined spectral interval and an image at each wavelength is stored. The resulting data hypercube is analyzed by proprietary principal component-based software.

## **Industrial Uses of NIR Instrumentation**

NIR spectroscopy is an application-driven technique and perhaps one of the greatest motive influences in the development of the many kinds of NIR instrument

has been their application to at-, on-, or in-line analysis for factory processes. Once a calibration has been developed, the NIR technique does not require chemicals and is capable of rapid, multicomponent, noninvasive analysis. Two features of NIR instrumental development are most significant in this context. The first is the increasing use of optical fibers, which enables the instrument to be multiplexed and/or remote from the line. Optical fibers are also used within instruments to optimize the light path geometry. The second feature is the development of nonmoving part or solid-state spectrometers that are light, rugged, long-lasting, small, and up to 10 times less expensive than their equivalents with moving parts. As has been noted, this type of instrument can also be developed to be handheld.

## **Industrial Applications of NIR Technology**

### **Applications in Agriculture and the Animal Feed Industries**

In the agriculture and animal feed industries NIR instruments, and in particular discrete filter instruments, have found the widest application in the analysis of grain and flour. Protein, moisture, hardness, and baking quality are all examples of analysis that have been performed by NIR instrumentation, both off- and online. Several countries, including the USA and Canada, have adopted NIR protein analysis as national standards to gauge the level of payment for wheat. The protein method was approved by the AACC (American Association of Cereal Chemists) in 1983.

In the feed and forage industries NIR methods have been used extensively. NIR factory-based quality control schemes have been implemented which enhance the economy with which feed components are used, and the quality and consistency of the final product. Moisture, crude protein, and acid detergent fiber analyses of feeds are being steered through the AOAC (Association of Official Analytical Chemists) validation process. NIR is also used widely in the US tobacco industry for measuring nicotine and other process parameters both on- and offline.

### **Applications in the Food and Beverage Industry**

It is perhaps the food and beverage industry that presents the most difficult challenge to both off- and online NIR analysis. The materials are organically complex, and often need to be analyzed in the presence of a high percentage of moisture, the broad, highly absorbing bands of which, in the NIR region, tend to obscure the lesser absorbing constituents.

**Table 1** Matrix of food products and components and characteristics analyzed offline and online by NIR

Food product	Acids $\alpha$ , $\beta$	Alcohol	Amino acids	Ash	Caffeine	Capsaicin	Casein	Cellulose	Chlorophyll	Color	Dietary fiber	Egg	Fat/oil	Fungal spores	$\beta$ -Glucan	Gluten	Hardness	Heat treatment	Hot water extract	Insects	Iodine value	Lactose	Methionine	Moisture	Nicotine	Nitrogen (total)	Nylon	Original gravity	Pasteurization	Polypropylene	Polythene	Proportions in a mixture	Protein	Salt	Sedimentation volume	Soya bean flour	Starch	Starch damage	Sucrose	Sulfur	Sugars	Tenderometer	Total solids	Water absorption

—, data not known; x, offline analysis; o, online analysis.

**Table 2** Overall quality parameters measured by NIR in food and animal feed

<i>Product</i>	<i>Quality parameter</i>
Cheese	Ripeness
Forage	Digestibility
Fruit, vegetables	Maturity
Fruit juices	Authenticity
Meat	Heat treatment
Milk	Pasteurization
Peas	Tenderometer readings
Seaweed (edible)	Quality
Spices	Gamma irradiation
Tea	Taster-defined quality
Wheat	Seed viability

In spite of the challenging nature of NIR analysis of food, applications of the technique are most common and diverse in this industry. **Table 1** lists NIR food applications both off- and online. **Table 2** lists those applications where NIR has been used to analyze for broad, relatively indefinable quality characteristics in food.

### Whole Fruit and Vegetable Analysis

Following on from the success with whole cereal grain analysis using NIR transmission technology, many workers have been using a variety of instrument types to obtain spectra from whole fruit and vegetables, nondestructively. Some success has been gained, for example, in measuring dry matter and sugar concentration in this way.

### Chemicals and Textiles

Quantitative analysis by NIR of petrochemicals dates back to the 1930s. Since then a range of NIR calibrations have been developed, for example, for octane number, methyl group analysis, and methanol content in petroleum. NIR has been used to monitor water, detergent solids, and glycerol in shampoo, and to analyze moisture and lubricant levels on polymer films. Process NIR spectrometers have been used to monitor naphtha composition and NIR instrumentation has been used to monitor ethylene polymerization.

For over a decade NIR quality control has been used in the textile and fiber industries. Perhaps the widest use of NIR has been in the cotton industry. Cotton blending, mercerization, and fiber maturity measurement have been used offline for rapid process control. The wool industry has also employed NIR to measure the residual grease after scouring. Calibrations have been developed for measuring moisture and heat set temperature in nylon yarn. Online NIR analysis is being developed for the quality control of the dyeing procedure for carpet yarn and for measuring yarn diameter.

### Pharmaceuticals and Medical Applications

Discriminant analysis of NIR spectra was used in 1986 to assay the level of lincomycin in a pharmaceutical formulation. This was the first NIR analysis to be accepted by this US Food and Drug Administration (FDA). NIR is now used to measure the salicylic acid content of aspirin and pharmaceutical companies use discriminant NIR procedures to check incoming raw materials for drug production. Sample identification can be achieved using at-line NIR fiber optic systems.

Antibiotic production in fermentations can now be monitored by NIR. A highly significant development in the medical field is the use of a handheld non-invasive NIR-based filter instrument for the monitoring of blood glucose levels for diabetics. Research is currently being undertaken to explore the feasibility of measuring human body temperature using NIR. Another potential medical application being examined is the measurement of oxygen levels in brain blood using a fiber optic probe placed on the skull. In the medical laboratory context, user-friendly fecal fat analysis is performed using NIR.

### Other Industrial Applications of NIR

An NIR method has been developed for measuring the hardwood content of bleached hardwood and the lignin content of unbleached hardwood pulp. Work has also been carried out using NIR reflectance spectra of hardwoods to discriminate between the different species. Using a Fourier transform NIR instrument carbonate measurements have been made on soil samples. NIR analysis of forest humus samples has provided satisfactory calibrations for microbial basal respiration, based on the organic polymer content of the humus. NIR analysis of the lake sediments for pH has been used to construct the lake water history.

The examples noted above are only a small fraction of the industrial applications of NIR, and the advent of solid-state instrumentation, will further widen the way in which NIR measurements can be made in an industrial context.

## Introduction

Photothermal spectroscopy is a class of optical analysis methods that measures heat evolved as a consequence of light absorption in an irradiated sample. In conventional spectrometric methods information is obtained by measuring the intensities of light transmitted, reflected, or emitted by the sample. In photothermal spectrometry, spectroscopic information is obtained by measuring the heat accompanying non-radiative relaxation. Because of the universality of the photothermal effect (e.g., heat evolution accompanies essentially all optical absorption), photothermal spectroscopy has diverse applications in chemistry, physics, biology, and engineering. Some applications and measurements in the analysis of solids are reviewed here.

## Theory

When a sample surface is heated with a periodically modulated beam, a thermal wave is generated which propagates away from the heated region. The thermal wave is a critically-damped temperature oscillation that, in a homogeneous material, decays exponentially with distance from the heated surface (Figure 1A). The thermal wave damping distance is the distance at which the temperature attenuates to 1/e of the value observed at the surface. This damping distance is controlled by varying the modulation frequency,  $\omega$  (rad/s), of the radiation source. For a sample of thermal diffusivity  $D$  ( $\text{m}^2/\text{s}$ ), the thermal wave damping distance,  $\mu$  (m), is given by

$$\mu = (2D/\omega)^{1/2} \quad [1]$$

With impulse heating, the time-dependent temperature profile below the heated surface has a Gaussian

dependence (Figure 1B) with a penetration distance,  $\mu_l$  (m), given by the time-dependent width of the Gaussian profile:

$$\mu_l = (2Dt)^{1/2} \quad [2]$$

### Introduction

Photothermal spectroscopy is a class of optical analysis methods that measures heat evolved as a consequence of light absorption in an irradiated sample. In conventional spectrometric methods information is obtained by measuring the intensities of light transmitted, reflected, or emitted by the sample. In photothermal spectrometry, spectroscopic information is obtained by measuring the heat accompanying non-radiative relaxation. Because of the universality of the photothermal effect (e.g., heat evolution accompanies essentially all optical absorption), photothermal spectroscopy has diverse applications in chemistry, physics, biology, and engineering. Some applications and measurements in the analysis of solids are reviewed here.

### Theory

When a sample surface is heated with a periodically modulated beam, a thermal wave is generated which propagates away from the heated region. The thermal wave is a critically-damped temperature oscillation that, in a homogeneous material, decays exponentially with distance from the heated surface (Figure 1A). The thermal wave damping distance is the distance at which the temperature attenuates to 1/e of the value observed at the surface. This damping distance is controlled by varying the modulation frequency,  $\omega$  (rad/s), of the radiation source. For a sample of thermal diffusivity  $D$  ( $\text{m}^2/\text{s}$ ), the thermal wave damping distance,  $\mu$  (m), is given by

$$\mu = (2D/\omega)^{1/2} \quad [1]$$

With impulse heating, the time-dependent temperature profile below the heated surface has a Gaussian

dependence (Figure 1B) with a penetration distance,  $\mu_l$  (m), given by the time-dependent width of the Gaussian profile:

$$\mu_l = (2Dt)^{1/2} \quad [2]$$

**Figure 1** (A) Spatial dependence of a single-frequency (harmonically driven) thermal wave. Frequency 20.0 Hz, diffusivity  $1 \times 10^{-3} \text{ m}^2 \text{ s}^{-1}$ . (B) Spatial dependence of the thermal wave observed at various times after application of a heat pulse. Diffusivity  $1 \times 10^{-3} \text{ m}^2 \text{ s}^{-1}$ . The instantaneous phase  $\phi = \omega t$ . (Reprinted from Power JF (1993) Scanning probes III: Photoacoustic and photothermal imaging. In: Morris MD (ed.) *Microscopic and Spectroscopic Imaging of the Chemical State*, pp. 255–302. New York: Dekker, courtesy of Marcel Dekker, Inc.)

Photothermal methods may be used for depth profiling spectroscopic and/or thermal properties of condensed-phase samples because the sampling distance of the thermal waves may be controlled by varying the modulation frequency (as in eqn [1]) or the observation time (as in eqn [2]).

For photothermal methods that monitor surface temperature changes, heat generation must occur approximately within the thermal wave damping distance of the sample's surface, in order to contribute to the measured signal. As  $\mu$  increases in an optically transmitting sample, the measured absorption spectrum of the sample may change, as more deeply buried layers contribute to the measured signal.

Photothermal spectroscopy may be used to measure physical and chemical properties of sample as a function of depth. This 'depth profiling' may be thermal, spectroscopic, or a composite of the two. Thermal depth profiling is achieved by irradiating the sample at opaque wavelengths. The magnitude and phase of the surface temperature is measured at several modulation frequencies and subsurface properties are deduced by subsequent data analysis.

For surface heated inhomogeneous samples, thermal waves experience reflection or absorption when they encounter buried interfaces wherein there is a change in the thermal effusivity ratio:

$$b_{ij} = \frac{k_i}{k_j} \left( \frac{D_j}{D_i} \right)^{1/2} \quad [3]$$

Indices  $i$  and  $j$  refer to adjacent layers,  $k_i$  and  $k_j$  ( $\text{W m}^{-1}\text{s}^{-1}$ ) are thermal conductivities, and  $D_i$  and  $D_j$  are the thermal diffusivities. Thermal effusivity is analogous to a refractive index for thermal waves. Reflection and absorption may be evaluated by the thermal reflection coefficient:

$$s_{ij} = (b_{ij} - 1)/(b_{ij} + 1) \quad [4]$$

$s_{ij} = +1$  for total reflection and  $s_{ij} = -1$  for total absorption of (plane) thermal waves incident on an interface. Subsurface reflection or absorption may result in measurable surface temperature change. Surface temperature changes obtained by scanning an excitation beam across the sample surface may contain subsurface information limited to the depth of the thermal diffusion length. The subsurface thermal image may thus be obtained by analysis of the surface temperature change.

In photothermal spectroscopy, optical absorption coefficients are obtained from the depth dependence of the subsurface heat produced by light absorption. In high-absorbance samples, light attenuates rapidly at short distances below the surface. Heat generation

is thus localized within surface layers. Surface heating produces rapid arrival of the heat to that surface. In low-absorbance samples, more heat is generated below the surface and there is a delay in the arrival of the associated heat at the sample surface. Corresponding changes also occur in frequency-domain signals, especially the phase of the photothermal response, which, at constant frequency, lags increasingly as light absorption occurs at increasing depths.

In a pulsed measurement, a general relationship exists between the depth of an optical-absorbing feature and the time required for heat conduction to the surface. This principle is illustrated in Figure 2 for the case of pulsed excitation, with the temperature measured at the rear surface of a sample composed of three different absorbing layers.

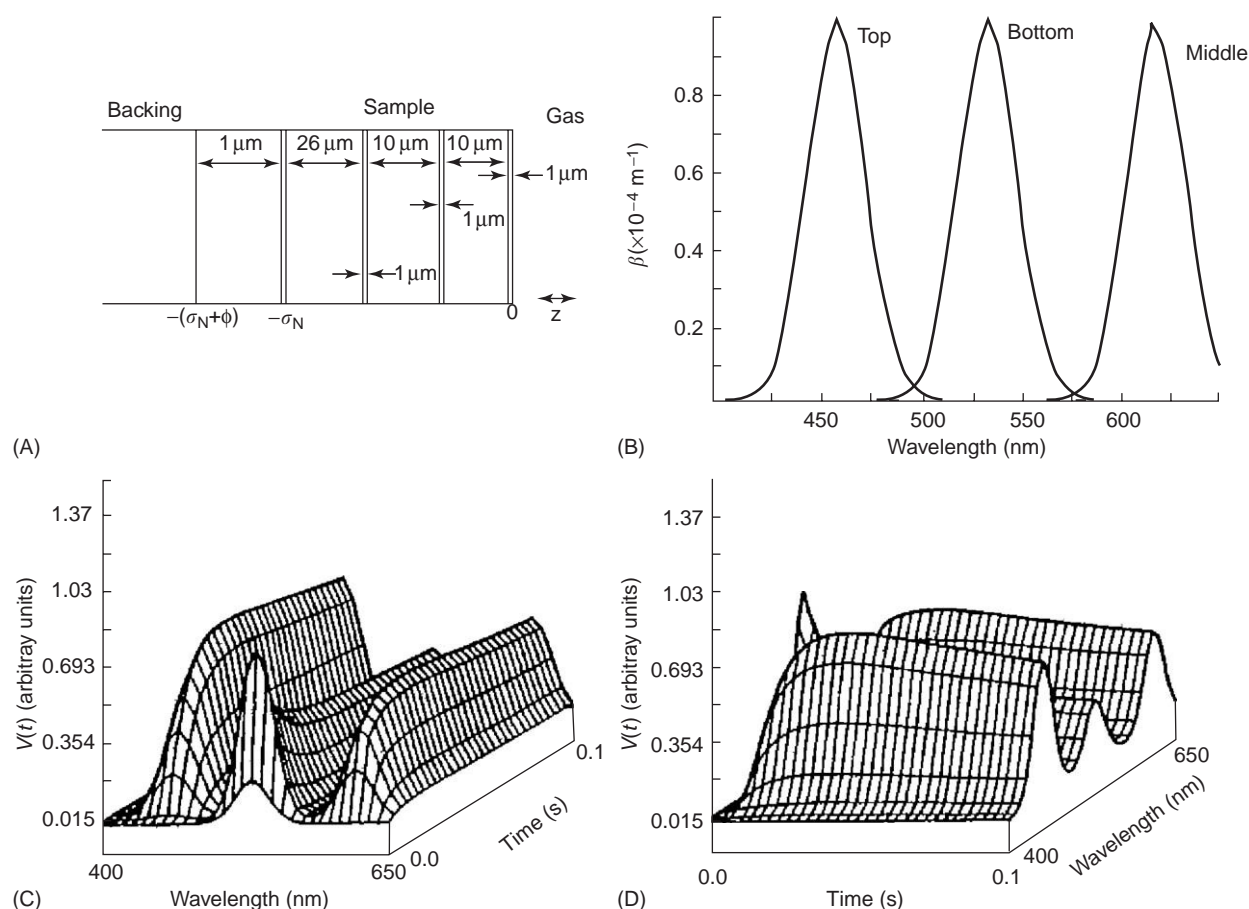

If the width of the irradiating beam is greater than the thicknesses of the layers probed and the variation of sample properties with distance is slow, the measured photothermal response data may be interpreted, in simple cases, by a theory derived by Rosencwaig and Gersho. In this case, the system is modeled as one-dimensional in optical absorbance and heat transport profiles. In this case, theoretical approaches for multiple layers are to be found in the literature. Continuous profiles of optical absorption or thermal diffusivity may be recovered from photothermal data by means of inversion methods.

## Instrumental Methods of Detection

Some processes that accompany the heat release from an irradiated condensed-phase sample are illustrated in Figure 3. The wavelength of this radiation may range from radiofrequency through to X-rays, although optical wavelength ranges are typically used. Heat may be detected directly by any one of a number of methods.

A direct detection strategy involves contacting a temperature sensor to the rear surface of the sample and monitoring the average temperature change in the sensor layer. Pyroelectric thin film sensor materials exhibit a polarization change that is approximately proportional to the average change in the temperature of the pyroelectric material. This change in polarization may be measured as a current or a voltage. This detection method, termed photopyroelectric spectrometry, has recently provided a rapid, sensitive method for the detection of thermal waves in very thin samples.

Heat conduction into the gas phase causes a modulated expansion of a layer of gas near the sample surface, producing a sound wave that can be detected using a microphone; the so-called photoacoustic effect. Thermally induced variations in the gas-phase

**Figure 2** Illustration of the theoretical photothermal response (C, D) at the rear surface of a multilayered sample (A). The optical absorption spectra of the various layers are given in (B). ( $V(t)$ , voltage response of the pyroelectric detector.) (Reprinted with permission from Power JF (1991) *Applied Spectroscopy* 45: 1240.)

density above the sample surface also produce refractive index gradients that may be probed through the deflection of an optical probe beam aligned parallel with the sample surface. This phenomenon is termed the mirage effect or photothermal deflection spectrometry.

For reflective samples, temperature changes may cause variations in the sample's reflectance giving rise to photothermoreflectance spectrometry. Increased blackbody emission accompanies sample heating by the excitation beam. An infrared detector may be used to measure this blackbody emission signal and to detect temperature changes in the sample caused by optical absorption. This remote method of detection is termed photothermal radiometry.

Finally, heat generation in the sample gives rise to a thermoelastic effect that may be detected by aligning a probe beam at the inflection point of the 'thermal bump' that is generated using a focused excitation beam. The probe beam is reflected from the sample surface and its deflection is monitored using a position-sensing detector. The deflection signal is

directly proportional to the derivative of the surface deformation, which in turn is proportional to temperature.

Good depth profile resolution requires a method that exhibits high sensitivity in combination with a wide instrumental bandwidth. The bandwidth of available modulation frequencies, over which a particular method is capable of response, is determined both by the electrical bandwidth of the transducers used for detection and the optical excitation geometry. Optical energy in the wavelength range from the ultraviolet to the IR may be used for signal excitation. Methods such as the mirage effect and photoacoustic spectroscopy are readily adaptable to detection using Fourier transform infrared (FTIR) spectroscopy.

It is possible to perform depth-resolved spectroscopy using these FTIR photothermal methods. Two commonly available instrumentation designs are used to perform FTIR photothermal spectroscopy. In constant scan rate FTIR photothermal instruments, the uniform motion of the movable interferometer mirror

**Figure 3** Schematic diagram showing processes accompanying heating of a sample by a modulated beam of radiation. (Reprinted from Power JF (1993) *Scanning probes III: Photoacoustic and photothermal imaging*. In: Morris MD (ed.) *Microscopic and Spectroscopic Imaging of the Chemical State*, pp. 255–302. New York: Dekker, courtesy of Marcel Dekker, Inc.)

causes a modulation of all infrared frequencies, each at a different modulation frequency. This produces difficulties in interpreting the measured photothermal signals. In step-scan FTIR photothermal spectroscopy, independent fixed modulation is imposed on the IR beam at each stationary position of the interferometer moving mirror as it is stepped through a scan. This greatly improves the ease of signal interpretation but requires more sophisticated instrumentation designs to ensure stable, repeatable interferometry measurements. Both intensity and wavelength modulation are used.

## Applications

Photothermal methods are used in a variety of applications that involve measurements of the thermal and optical properties of thin specimens. As materials are subjected to processes such as annealing, cross-linking, extrusion, photodegradation, diffusion, etc., the thermal diffusivity of the sample may change significantly, especially in near-surface regions. In many cases,  $D$  may decay strongly with depth below the surface in a bulk sample, or spatially. Thermal conductivity is especially sensitive to these physical changes, although variations in density and heat capacity may also be involved. Variations in thermal conductivity generally give rise to primary changes in the thermal efflux ratio (eqn [3]), which

can be imaged spatially by photothermal techniques. Conventional thermoanalytical methods, in contrast, probe only the average properties of the bulk sample.

Anisotropy in thermal diffusivity provides the basis for a novel and interesting photothermal imaging method. Fibrous materials and crystals, for example, may have a preferred axis for heat conduction. In materials that have been subjected to tensile loading, an enhanced thermal conductivity may lie along the stretch axis.

Infrared photothermal radiometry can be used to measure thermal anisotropy, by displacing excitation and detection spots on the sample, and measuring the transverse heat flow between these spots. As the direction of the spot displacement is varied, directional variations are sampled. Entire images of the thermal anisotropy may be scanned using this method. Such images may be used to detect defects in aligned materials, where a defect destroys the local alignment of bulk fibers or molecular chains.

A number of photothermal applications exist in the remote inspection and evaluation of materials. Video radiometry has been used for rapid inspection of large area samples such as sheet metal panels, vehicle bodies, or engine components. Metallurgical samples give good examples of materials that are routinely subjected to a variety of processing stages that may include hardening, annealing, mechanical deformation, etc. Photothermal radiometry has been used to inspect welding seams and to estimate seam thicknesses using a single-ended measurement.

Microstructural changes produced in mechanically deformed metals produce significant variations in their thermal properties, which can be detected using photothermal imaging.

Modulated thermorefectance and thermoelastic effect imaging have found important applications in the nondestructive inspection of semiconductors.

Thermal wave imaging may be used to inspect ion implantations, to evaluate defects in silicon, and to acquire depth-dependent images of integrated circuit features, or as a general probe for the study of non-radiative processes in semiconductors. Devices may be inspected in active mode (e.g., with current flowing).

Photothermal imaging has also found applications in the study of practical industrial materials, including fibers, ceramics, and composites, where the depth dependence of the recovered image may be useful in identifying surface features due to mechanical or oxidative processes, or subsurface defects and delamination.

The depth profiling capabilities available with photothermal methods have found important applications in biology and biophysics. Photoacoustic and

photothermal spectroscopy have evolved in recent years as general tools for the study of photosynthesis and energy conversion by plant photosystems.

Depth profile analysis using photothermal methods has contributed a number of nondestructive methods for studying the spectroscopy of plant tissues. The phase rotation method of signal recovery has been used to examine a number of specimens of botanical interest, including leaves, tissues, and lichens.

Tissues such as skin have also been studied using photothermal methods, especially IR radiometry, which is capable of noncontact measurement, and is robust to alignment instabilities. In addition to the thermal and optical depth profiling of the various layers of the skin, photothermal spectroscopy has been used to study the time-dependent penetration of topically applied cosmetics and sunscreens below the skin surface. Photothermal studies have been used to monitor the time for which a topically applied film exists as a discrete phase on the outer surface of the skin.

Other examples of tissues that have been investigated with photothermal methods include ocular and arterial tissues. IR photothermal radiometry, in particular, shows promise as a general diagnostic tool in biomedical studies, in the nondestructive imaging of very thin layers.

### Introduction

Infrared spectroscopy is widely used in industry. The applications range from quality control and quality assurance of raw materials to customer complaints (troubleshooting) to quantitative analysis and online process monitoring and control. Most of the instrumentation is based on a Fourier transform infrared (FTIR) spectrometer but specialist applications use instruments as diverse as a nondispersive infrared detector through to mid-infrared diode lasers.

In this section, the emphasis will be on applications that make use of the power of infrared spectroscopy to give information about the molecular

species present. The huge advantage in signal-to-noise ratio (per unit time) of FTIR spectrometers over dispersive instruments means that virtually all industrial applications use FTIR. This means that techniques that result in low signal levels, such as attenuated total internal reflectance or, especially, infrared microscopy, can generate spectra of sufficient signal-to-noise ratio in a reasonable time as to be viable analysis methods.

### Sample Types

The range of samples that are encountered in industry spans all three states of matter: solid, liquid, and gaseous. The key point is that, with sufficient effort, it is possible to obtain an infrared spectrum from most materials. For instance, while a metal does not exhibit an infrared spectrum, the oxide layer present at the surface can be characterized by infrared

### Introduction

Infrared spectroscopy is widely used in industry. The applications range from quality control and quality assurance of raw materials to customer complaints (troubleshooting) to quantitative analysis and online process monitoring and control. Most of the instrumentation is based on a Fourier transform infrared (FTIR) spectrometer but specialist applications use instruments as diverse as a nondispersive infrared detector through to mid-infrared diode lasers.

In this section, the emphasis will be on applications that make use of the power of infrared spectroscopy to give information about the molecular

species present. The huge advantage in signal-to-noise ratio (per unit time) of FTIR spectrometers over dispersive instruments means that virtually all industrial applications use FTIR. This means that techniques that result in low signal levels, such as attenuated total internal reflectance or, especially, infrared microscopy, can generate spectra of sufficient signal-to-noise ratio in a reasonable time as to be viable analysis methods.

### Sample Types

The range of samples that are encountered in industry spans all three states of matter: solid, liquid, and gaseous. The key point is that, with sufficient effort, it is possible to obtain an infrared spectrum from most materials. For instance, while a metal does not exhibit an infrared spectrum, the oxide layer present at the surface can be characterized by infrared

reflectance methods; while hydrogen gas does not have an infrared spectrum at ambient pressure, it does when chemisorbed into a zeolite.

Solid samples can be a bulk material such as a polymer or a raw material, they can be a surface coating such as varnish buildup on a piston or a particle on a semiconductor wafer. Liquids can be pure or as a solution or mixture. Gases can be pure or a mixture, such as in stack gases; they may also be very dilute, down to  $\text{mg l}^{-1}$  (parts per million) level for trace gas analysis such as for atmospheric monitoring or breathing gas for divers. In addition to these possibilities, it may be necessary to carry out the analysis at temperature and pressure conditions well removed from ambient. A final complication is that pure samples are rarely encountered; much more common are mixtures, often with the material of interest present as the minor component.

## Sample Preparation

In industry, time is at premium so the emphasis is always to carry out the analysis in the most efficient manner possible. In practice, this means that the analyst employs the sampling method that requires the least possible sample preparation. Historically, the great majority of liquid samples were run as thin films between infrared transparent plates (usually KBr) or in fixed pathlength cells. Similarly, most solid samples were run as KBr discs, as mulls or as a thin film deposited from solution onto a suitable substrate. Polymers were usually hot-pressed to make a self-supporting film, with a thickness typically between 0.020 and 1.0 mm; the former being used for the identification of a bulk material and the latter for the identification of minor components, contaminants, or degradation products.

Sample preparation was greatly simplified in the late 1990s by the introduction of commercial diamond attenuated total internal reflection (ATR) systems. These use a small diamond as a single-pass ATR element held in a metal plate. The sample is placed on the diamond, a plate is then brought down onto it and clamped in position. This ensures excellent contact between the ATR element and the sample, so immediately eliminates the problem of poor contact that made ATR so problematical for use with solids, particularly powders. The accessory can be permanently installed in the purged sample compartment of the spectrometer, so there is only a very short pathlength that is in the open air. This means that there is no need to wait for the sample compartment to purge to reduce the atmospheric water and carbon dioxide absorption. The result is that the sample can be placed in the accessory and scanned immediately,

so that even unskilled operators can obtain reliable results. The method is readily applicable to all solid and semisolid materials including powders, pellets, sheets or film, pastes, and gels. Liquids are readily studied and the inertness of diamond also allows corrosive materials to be examined. The only disadvantage is the small number of reflections, and hence pathlength, which means that only the major components will be seen; thus, it is unsuitable for systems that are dilute in the material of interest.

However, there are cases where more involved methods have to be used. An example would be a contaminant in a piece of plastic piping. If the particle is large enough ( $>0.1$  mm) then it can be physically separated for subsequent analysis. Smaller particles are extremely difficult to manipulate and it is advantageous to examine them *in situ* if possible. It is then necessary to make a thin section, either by using a scalpel or, better, by microtoming the material followed by examination in an infrared microscope. This is an optical microscope that is interfaced to an FTIR spectrometer such that the visible and infrared radiation follow identical paths through the sample. The use of visible microscopy allows the area of interest to be located and then isolated by aperturing in an image plane. A mirror-flip then directs the infrared light along the same path. The instrument usually has a dedicated high sensitivity detector to improve the signal-to-noise ratio. An infrared microscope is now an essential part of the equipment in most industrial chemical laboratories.

Other methods that are used less frequently include diffuse reflectance and photacoustic spectroscopy. These are treated in detail elsewhere in this encyclopedia and each have their own sampling problems. In favorable cases it is possible that no sample preparation is required; more often, better results are obtained if the sample is ground to a fine powder. This often requires a mechanical grinder, sometimes at liquid nitrogen temperature.

## Applications

Infrared spectroscopy has two main uses in industry: qualitative and quantitative analysis. Qualitative analysis may range from the identification of contaminants in products, to the analysis of a competitor's product, to the study of reaction mechanisms. Quantitative analysis may be used in any physical state for components that may be the bulk of the sample to those present in parts per million concentrations. In the remainder of this section examples of both classes of analysis will be discussed; these are intended to give an appreciation for the approach that is used and the type and range of problems that can be addressed.

A simple type of qualitative analysis is the question; 'are these two materials the same?' This is a key question in the pharmaceutical industry where the occurrence of polymorphism is rife. Polymorphism is the existence of two or more crystal forms of the same compound but with distinct structures. To ensure patent protection of a new drug, all polymorphs need to be characterized. Polymorphs of the same compound may have different physical properties such as solubility and hence bioavailability. Paracetamol (4'-hydroxyacetanilide, see **Figure 1**) is a widely used drug for the relief of mild pain and reduction of fever. It has two important polymorphs, which are the commercially used Form I (monoclinic) and Form II (orthorhombic). The latter, unlike commercial paracetamol (Form I), undergoes plastic deformation and is suitable for direct compression. Consequently, Form II has attracted much interest because of the potential commercial benefits to be gained by not using binders during the manufacture of tablets. As **Figure 1** shows, the two polymorphs are readily distinguished by infrared spectroscopy and this is often the case with polymorphs.

A second area where this type of question is of crucial importance is in forensic science. Infrared spectroscopy and, particularly, infrared microscopy are key techniques used for identification and comparison of fibers and paint types.

Infrared spectroscopy is also used to answer much more complex questions. It has long been used to investigate heterogeneous and homogeneous catalytic processes because it is often possible to study the reaction under industrially relevant conditions of temperature and pressure. The low pressure rhodium and iodide catalyzed carbonylation of methanol to acetic acid is a major industrial process with a large proportion of the annual production of 5 000 000 tons of acetic acid being made by this route. The overall mechanism is known (see **Figure 2**), but rates for all the individual steps were not. Infrared spectroscopy was able to show that the oxidative addition of  $\text{CH}_3\text{I}$  with the starting complex A was the rate determining step, since the resulting intermediate B decays at the same rate as A showing that the migratory insertion of CO into the  $\text{Rh}-\text{CH}_3$  bond is fast. Using a combination of *in situ* infrared and  $^{13}\text{C}$  nuclear magnetic resonance spectroscopies, it was possible to measure rate constants for all the steps and activation parameters for the migratory insertion.

In the polymer industry a recurring problem is the presence of particles in the product. An example is shown in **Figure 3**. The particle was  $\sim 0.1$  mm in diameter and was embedded in a poly(aryl ether sulfone) film. The spectra are very similar, showing that the particle is not an inorganic contaminant. The decreased absorbance at  $760\text{ cm}^{-1}$ , shows that the

**Figure 1** Infrared spectra of (A) Form I and (B) Form II of paracetamol (4'-hydroxyacetanilide), bands indicated by arrows are significantly different in intensity or position in Form II as compared to Form I.

**Figure 2** Series of infrared spectra showing the reaction of  $[\text{Bu}_4\text{N}][\text{Rh}(\text{CO})_2\text{I}_2]$  in neat  $\text{CH}_3\text{I}$ . Note that the weak peak at  $2104\text{ cm}^{-1}$  assigned to the key intermediate B decays at the same rate as the starting complex A. The bands of C at  $2061$  and  $1740\text{ cm}^{-1}$  are complex because of a mixture of isomers. The inset shows the catalytic cycle. particle is deficient in the aryl-Cl end-group. The most likely explanation is that the particle is of higher molecular weight, which has a different rheology during processing.

A better understanding of a system can often be gained by studying the spatial distribution of a component. Infrared microscopy is a very powerful tool for such investigations. In this case, the spectrum of

**Figure 4** FTIR microscopy of polyethylene cable insulation. (A) Water-tree, (B) undamaged area, and (C) the difference spectrum (A) – (B). (Parker SF (1995) Industrial applications of vibrational spectroscopy and the role of the computer. In: George WO and Steele D (eds.) *Computing Applications in Molecular Spectroscopy*, pp. 181–199. Cambridge: The Royal Society of Chemistry; reproduced by permission of The Royal Society of Chemistry.)

the sample is recorded at a large number of points and a map is generated from the spectra by plotting the intensity of a spectral feature as a function of its position. This process can be carried out manually; however, it is much better done automatically using an XY stage interfaced to the spectrometer's computer. This process is relatively slow and to map an area of  $1 \text{ mm}^2$  with a relatively coarse step size of  $0.1 \text{ mm}$  requires collection of 100 spectra, which will take at least an hour. Since most of the infrared beam is lost at the apertures that define the spot size, the signal is weak, so longer measurement times are needed and often the best solution is an overnight run.

An example of the utility of infrared mapping is shown in Figures 4 and 5. A failure mode of cross-linked polyethylene used for electrical cable insulation is water-treeling. Water-trees are damaged areas that when boiled in water and imaged with an optical microscope have a dendritic appearance. Figure 4 shows infrared spectra recorded from a microtomed section of a water-tree; Figure 4A is from the water-tree, Figure 4B from an undamaged area, and the difference spectrum is shown in Figure 4C. A strong band at  $\sim 1600 \text{ cm}^{-1}$  in Figure 4C suggests the presence of carboxylate. The region of the water-tree was then mapped and the ratio of the  $1600 \text{ cm}^{-1}$  band to that of a polyethylene band at  $2020 \text{ cm}^{-1}$  (to eliminate the effect of thickness variations in the section) plotted, as shown in Figure 5A. If the  $1600 \text{ cm}^{-1}$  band is associated with carboxylate formation, then there must be a counterion. Proton

**Figure 5** (A) Contour plot of the distribution of carboxylate ions in the water-tree by FTIR microscopy. (B) Proton-induced X-ray emission image of the sample showing the distribution of potassium. Note the similarity to (A). (Parker SF (1995) Industrial applications of vibrational spectroscopy and the role of the computer. In: George WO and Steele D (eds.) *Computing Applications in Molecular Spectroscopy*, pp. 181–199. Cambridge: The Royal Society of Chemistry; reproduced by permission of the The Royal Society of Chemistry.)

induced X-ray emission of the sample showed the presence of potassium with a distribution very similar to that of the carboxylate as shown in Figure 5B, providing a plausible counterion and confidence in the assignment to carboxylate. The results suggest

that water-treeing results from localized oxidation that changes the polymer from hydrophobic to hydrophilic. Water and ions can travel along and condense into these hydrophilic paths; repetition of the process propagates the water-tree as a myriad of such channels.

This example indicates two recurrent themes in industrial infrared analysis: the use of computer subtraction to look for differences between two (or more) samples is probably the most commonly used form of data manipulation in infrared spectroscopy. The second feature is that one technique in isolation is rarely capable of providing the entire answer, much more often data from a variety of sources must be combined in order to arrive at the solution.

The major area of growth in the use of vibrational spectroscopy in recent years has been in the application to biology. The identification of bacteria and other microbiological organisms is well established. Over 800 yeast strains can be identified with high certainty and bacteria can be classified and identified by infrared methods.

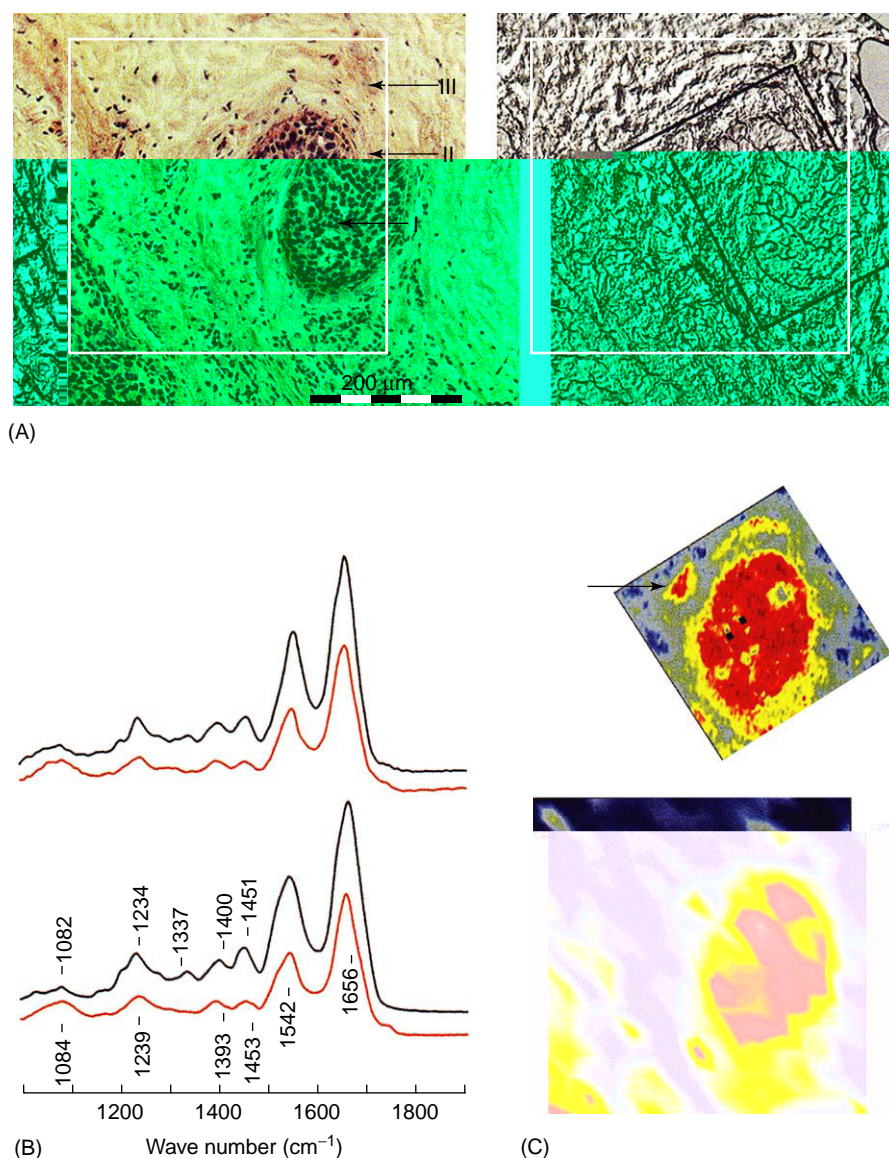

There is enormous interest in the use of infrared microscopy to distinguish tissue types. As an example, **Figure 6** shows a section through the retina of a pigmented rat and the corresponding spectra. The bands labeled A–F have different relative intensities in the spectra. The outer segments (OS, spectrum 1) of retinas from pigmented animals were found to have unusually strong absorption values for C=C–H unsaturation (band B) and carbonyl functional groups (band D). Docosahexaenoic acid ( $\text{CH}_3(\text{CH}_2\text{CH}=\text{CH})_6\text{CH}_2\text{CH}_2\text{CO}_2\text{H}$ ) is a major constituent of lipids in the outer segments which suggests that it is responsible for those enhanced absorption

values. Absorbance values for the unsaturation and carbonyl functional groups were substantially reduced in the outer segments of retinas from albino animals. This finding, together with data from other studies on light-induced oxidative events in the retina, indicates a loss of docosahexaenoic acid by a light-induced mechanism in albino animals. The outer nuclear layer (ONL, spectrum 3) had strong absorbance values for H–C–OH (band F) and P=O functional groups (band E), which are assigned to the sugar phosphate backbone of DNA. The outer (OPL, spectrum 4) and inner plexiform layers (IPL, spectrum 6) were found to contain greater concentrations of  $\text{CH}_2$  (band C) and C=O functional groups (band D) than the outer (ONL, spectrum 3) and inner nuclear layers (INL, spectrum 5), which is due to the high concentration of synaptic connections in the former layers. Thus, there is a unique chemical profile in the outer segments compared to other retinal layers, and this profile is different in albino animals.

The challenge is to be able to distinguish normal, precancerous, and cancerous cells. This has proven very difficult and there have been a number of false starts. Part of the problem is that cancerous and normal cells are of different size, so scanning a section with a fixed aperture does not result in spectra that are representative of the various types. To overcome this problem, attention has switched to infrared imaging rather than mapping. An imaging spectrometer uses a focal plane array of detectors, usually  $64 \times 64$  detectors, each  $0.055 \times 0.055$  mm. Each pixel in the acquired image corresponds to a region in the sample of  $0.005 \times 0.005$  mm, which is smaller than a single cell. It is also close to the diffraction limit, so caution in interpreting the spectra is needed.

**Figure 6** A series of spectra (right) from the various layers of a pigmented rat retina (left). Spectra were collected from photoreceptor outer segments (OS, spectrum 1), inner segments (IS, spectrum 2), outer nuclear layer (ONL, spectrum 3), outer plexiform layer (OPL, spectrum 4), inner nuclear layer (INL, spectrum 5), and inner plexiform layer (IPL, spectrum 6). Note the elevated absorbance values for C=C–H (B),  $\text{CH}_2$  (C):NH (A), C=O (D) in the outer segments and the elevated absorbance values for P=O (E) and H–C–OH (F) in the outer nuclear layer. The  $\text{CH}_2$ :NH ratio is also large in the inner plexiform layer. (Reprinted with permission from LeVine SM, Radcliff JD, Sweat JA, and Wetzel DL (1999) Microchemical analysis of retina layers in pigmented and albino rats by Fourier transform infrared microspectroscopy. *Biochimica et Biophysica Acta-General Subjects* 1473: 409–417; © Elsevier.)

**Figure 7** (A) A stained (left) and unstained (right) cryosection of breast tissue with ductal carcinoma. The unstained section was mapped using the point-by-point method (area in white square) and by the imaging method (area in black square). Spectra of the normal (upper spectrum of each pair) and tumor (lower spectrum of each pair) areas by the imaging method (upper pair) and by the point-by-point method (lower pair) are shown in 'B' and the corresponding images (upper: imaging, lower: point-by-point) in 'C'. The images are based on the peak intensity at  $1084\text{ cm}^{-1}$ , normalized to the integrated intensity between  $1000$  and  $1900\text{ cm}^{-1}$ . (Reproduced with permission from Fabian H, Lasch P, Boese M, and Haensch W (2002) Mid-IR microspectrometric imaging of breast tumour tissue sections. *Biopolymers* 67: 354–357; © John Wiley & Sons Ltd.)

Figure 7A shows a stained (left) and unstained (right) cryosection of breast tissue with ductal carcinoma. The unstained section was mapped in the point-by-point method (area in black square) and by the imaging method (area in white square). Spectra of the tumor and normal areas by both methods are shown in Figure 7B and the corresponding images in Figure 7C. The images are based on the peak intensity at  $1084\text{ cm}^{-1}$ . Both methods detect the presence of the tumor; however, additional fine structure is revealed in the focal plane array image. This is

because the aperture size used for the mapping method was  $0.030\text{ mm}$ , so many pixels in the image are a composite of the spectra of tumor + normal cells.

Quantitative analysis can take many forms but the basis of most analyses is the Beer–Lambert law:

$$A = \log_{10}(I_0/I) = \epsilon cl \quad [1]$$

where  $A$  is the absorbance of the band,  $I_0$  and  $I$  are the incident and transmitted intensities, respectively,  $\epsilon$  is the absorptivity,  $c$  is the concentration, and  $l$  is

the pathlength. The major difficulty is that the concentration of a species is related to its spectral intensity (at a given wavenumber) by the absorptivity, which is wavenumber dependent. While it is possible to calculate these by *ab initio* methods, in practice this is only possible for small molecules containing light atoms. This means that standards have to be generated by an independent method. This frequently causes considerable difficulties because the necessary reference materials are not available.

One area that quantitative infrared analysis is used routinely is in the semiconductor industry. Major applications include the determination of impurities, the quantitation of dopants, and epitaxial thickness measurements. Oxygen and carbon measurements in silicon are carried out routinely and at least two FTIR spectrometer manufacturers supply small dedicated instruments for this purpose. Oxygen atoms in interstitial sites absorb at  $1107\text{ cm}^{-1}$  and carbon atoms in substitutional sites in the silicon lattice at  $605\text{ cm}^{-1}$ . The bands are readily detected in a difference spectrum between the sample wafer and a high-purity reference wafer grown by the float-zone method. Considerable effort has gone into making these measurements quantitative with the result that they can be routinely determined down to  $5 \times 10^{16}\text{ atoms cm}^{-3}$ . At liquid helium temperatures the oxygen bands sharpen considerably, improving the detection limits but at a considerable cost in complexity.

An area that will become increasingly important is the use of infrared spectroscopy for online and at-line analysis. Most of the novel applications of FTIR to industrial process analysis are proprietary. An example that illustrates the advantages of process FTIR is

to the analysis of impurities in anhydrous vapor-phase HCl. Typically, a large-scale isocyanate plant will produce  $>10^5$  tons of anhydrous HCl per annum and it is essential to the profitability of the plant that the HCl is utilized. One use for anhydrous HCl is production of 1,2-dichlorethane via the catalytic oxychlorination of ethylene. To be suitable as a raw material, the HCl must meet rigid quality specifications, as some impurities act as catalyst poisons. In addition to HCl, the components of interest include: phosgene, Freon 12, CO, CO<sub>2</sub>, and unknown organics such as process solvents. 'Ruggedized' FTIR spectrometers are commercially available and one was used for this application. The sample cell was a 20 cm gas cell with BaF<sub>2</sub> windows. The instrument was calibrated for five components and the precision achieved is shown in Table 1.

Figure 8 shows an online infrared spectrum of HCl. The wide dynamic range afforded by FTIR allows both intense bands such as the first overtone of the H–Cl stretch of the bulk sample and weakly absorbing bands such as the carbonyl stretch of phosgene to be used. It was recognized that variations in gas pressure will affect the analysis result because of gas law effects and spectral line shape changes. Pressure

**Table 1** Compounds monitored by FTIR in anhydrous gaseous HCl

Component	Range	Precision achieved
Hydrogen chloride	90–100%	0.56%
Carbon dioxide	0–5%	0.04%
Carbon monoxide	0–5000 ppm	3 ppm
Freon	0–500 ppm	2.2 ppm
Phosgene	0–500 ppm	1.7 ppm

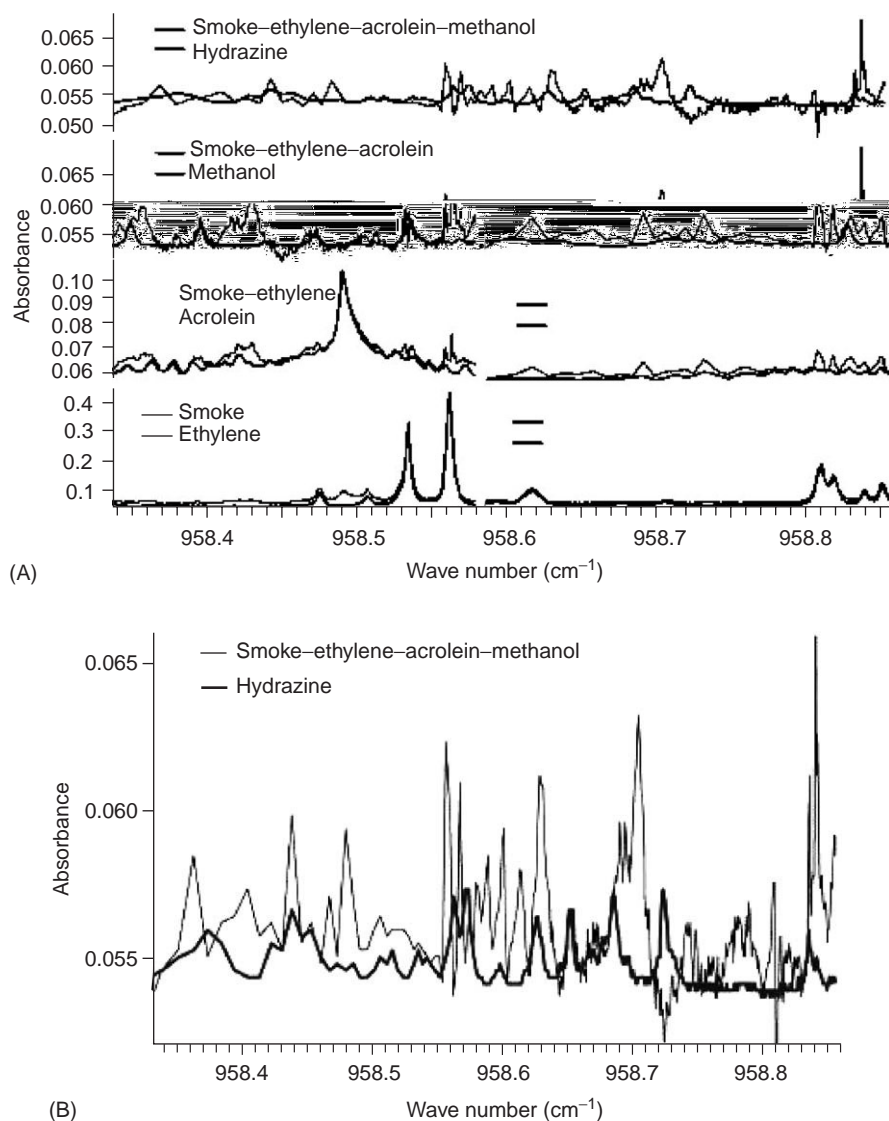

**Figure 8** An online spectrum of anhydrous HCl at 30 psig. (Reproduced with permission from Tate JD, Chauvel P, Guenard RD, and Harner R (2002) Process monitoring by mid- and near-infrared Fourier transform spectroscopy. In: Chalmers JM and Griffiths PR (eds.) *Handbook of Vibrational Spectroscopy*, vol. 4, pp. 2737–2769. Chichester: Wiley; © John Wiley & Sons Ltd.)

effects were compensated for in two ways: a carefully engineered sample system was used to regulate the sample pressure to  $3 \times 10^5$  Pa (35 psig) and the pressure in the sample cell was measured using a high-resolution pressure transducer. The calibration was developed by collecting spectra at 15 concentrations for each component at  $2.7 \times 10^5$  Pa (25 psig),  $3 \times 10^5$  Pa (30 psig), and  $3.3 \times 10^5$  Pa (30 psig). The calibration model itself was a set of partial least squares models, one for each component.

Infrared diode lasers offer high resolution,  $0.001 \text{ cm}^{-1}$  or better, ppb ( $10^{-6} \text{ g l}^{-1}$ ) detection limits and millisecond time resolution. These characteristics are ideally suited to low-pressure,

gas-phase measurements of light (five atoms or less) molecules. They find application in trace gas measurements of atmospheric species and also for measurements of isotopic species in human breath. An unusual application is to the determination of the components of inhaled cigarette smoke. **Figure 9A** shows the progressive removal (spectral stripping) of ethylene, acrolein, methanol, and comparison with a hydrazine spectrum. **Figure 9B** shows an expanded view of the final spectrum compared with that of hydrazine, which has been reported in cigarette smoke. It is apparent that there is at least one other component that has not been accounted for, but that this is not hydrazine.

**Figure 9** (A) Spectral stripping of components from the tunable diode laser infrared spectrum of cigarette smoke. From bottom to top: ethylene, acrolein, methanol, and comparison with hydrazine. The reference spectrum is the lower of the two traces in each case. (B) Expanded view of the residual spectrum compared to that of hydrazine. ## Trends in the Use of Infrared in Industry

There are three different types of infrared spectrometer available: dispersive, interferometric, and laser based. The present situation is that FTIR dominates the market. The reasons for this are that the combination of price, performance, and versatility offered by FTIR is unmatched by any competing technology. This trend is likely to continue for at least the next five years and probably the next decade. FTIR is a mature technology and most chemical laboratories have, at least, a simple bench-top unit as a piece of routine analytical equipment. There will be an increasing use of 'black-box' analyzers where the sample is inserted and an answer is produced. The fact that the box is actually an FTIR spectrometer will be largely irrelevant to the user; it will be a tool in the same way that a balance or a pH meter is. This is already happening; dedicated instruments for used oil analysis, semiconductor analysis, and on-bead analysis in combinatorial chemistry are commercially available.

The use of chemometrics will continue to increase and is almost mandatory for online applications. The spectral stripping of cigarette smoke could be done using a chemometrics approach rather than by sequential subtraction. The advantage is that all the components would be determined simultaneously without the laborious and somewhat subjective subtractions. The disadvantage is that the work to setup the method is somewhat greater; however, for a large number of samples this would be recovered in reduced time per analysis and the use of less skilled personnel. The trade-off between time to setup the method and time to carry out the analysis is the usual case.

Throughout the chemical industry there is an accelerating trend to obtaining data about a process online so that the process can be optimized in real time. Largely because fiber optic technology that can be used over hundreds of meters already exists, near-infrared and Raman spectroscopies are finding increasing application for this purpose; however, the mid-infrared is potentially much more informative. The major limitation is the length of the fibers that can be used before the losses become unacceptable. ZrF<sub>2</sub> fibers may be used up to 10 m or so but only allow the O-H and C-H stretching regions to be observed. Chalcogenide (AsSbSe) glasses allow the mid-infrared to 1200 cm<sup>-1</sup> to be measured but can only be used with a total length of a few meters. An alternative is that used for the HCl analysis: bring the sample to the spectrometer. This has engineering implications but results in much better spectra.

The sea change in infrared spectroscopy has been the explosion of applications in biology. One of the

major goals is diagnosis, particularly of cancer. The small size of cancer cells makes this difficult so two complementary approaches are being employed. Infrared synchrotron radiation is much brighter (photons cm<sup>-2</sup>) and better collimated than the thermal sources used in spectrometers. This allows spectra with high signal-to-noise ratio to be recorded down to the diffraction limit, ~0.005 mm. The second is the use of infrared microscopes with a focal plane array of detectors to collect images. These are then subjected to a variety of advanced data processing algorithms. The medical and commercial potential of automated diagnosis is so large that this is likely to be the application that dominates infrared spectroscopy for the next decade.

### Introduction

Ion exchangers are solid materials or liquid solutions which are able to take up (or absorb) positively or negatively charged ions from aqueous electrolyte solutions and at the same time release other ions of equivalent amount into the aqueous solution. According to the electric charge of the ions taking part in the ion exchange process, one can speak about cation and anion exchangers. Ion exchangers which are able to interact with both types of ions are called amphoteric.

The ideal ion exchange process proceeds stoichiometrically, i.e., the ratio of the ions exchanged between the two phases is strictly determined by their charges. A clear distinction can be made between ion exchange and adsorption or liquid–liquid extraction processes, in which molecules are transferred from the aqueous phase into the solid, or organic solvent phase, without releasing any other species into the aqueous solution.

Ion-exchange processes are important in biological systems of living organisms. They are important not

only from the point of view of selective secretion of some biological substances, but also in the transport mechanism of certain ions crossing cell membranes, and also in the signal expansions in nerve systems.

Ion exchange processes have importance also in agriculture, because the ion-exchange properties of the natural silicates present in the soils highly influence the composition of the interstitial liquid available for the feeding of the plants.

Synthetic ion exchangers have proved to be very useful tools both in industry and in the laboratory, because by means of ion exchangers the concentration of certain ions in solution can be changed very easily without unwanted disturbances of the total composition of the electrolyte, and also selective separations, extractions, and enrichment procedures can be carried out with them.

### History

Key events in the development of ion exchangers and also that of their analytical applications are tabulated in chronological order in Table 1.

### Types of Ion Exchangers

The current synthetic ion exchange materials can be classified according to their form into the following main groups:

- solid beads or particles,
- solid membranes,
- solid sheets (papers or layers), and

- organic solvent solutions of ion exchange compounds (liquid ion exchangers).

The conventional ion exchangers belong to the first group. (The fibrous or powder solid ion exchangers are of much less importance.) These ion exchangers can be classified according to their chemical compositions (matrices), and to their functional groups as follows:

1. Ion-exchange resins with condensation type (phenol-formaldehyde) or with polymerization type (styrene-divinylbenzene copolymer or methacrylate-divinyl-benzene copolymer, etc.) matrix. The strongly acidic cation exchangers have sulfonic acid groups, the weakly acidic cation exchangers carboxylic or phosphonic acid groups. The strongly basic anion exchangers usually have quaternary ammonium groups, while the weak exchangers have primary, secondary, or tertiary amine groups. Chelating resins have chelate-forming functional groups containing O, N, or S donor atoms. Amphoteric ion-exchange resins have both acidic (cation exchanger) and basic (anion exchange) groups.
2. Cellulose-based ion exchangers. Their chemical structure is a hydrophilic cellulose network having acidic (carboxymethyl, sulfoethyl, etc.) or basic (amino-ethyl, diethylaminoethyl, etc.) groups.
3. Dextran- or agarose-based ion exchangers. The matrix is cross-linked hydrophilic dextran or agarose and the attached functional groups are acidic or basic, similar to those mentioned for the cellulose ion exchangers, for cation and anion exchangers, respectively.

4. Inorganic ion exchangers. Inorganic cation exchangers include the zeolites (crystalline hydrated aluminosilicates) and acid salts of polyvalent metal ions (like zirconium phosphate, titanium tungstate, nickel hexacyanoferrate(II), etc.), salts of some hetero-polyacids (ammonium molybdophosphate, etc.). The hydrous oxides of tri- and tetravalent metal ions show cation and anion exchange properties depending on the nature of the metal ion and on the pH of the solution.

5. Surface-functionalized ion exchangers. Surface-functionalized ion exchangers are produced for high-performance ion exchange chromatography as column packing materials. Usually they are spherical beads with an inert core (styrene divinylbenzene copolymer or silica) and a thin surface layer of ion exchanger properties, having acidic or basic functional groups serving as cation or anion exchangers, respectively. The functional groups can be chemically bonded directly onto the matrix of the ion-exchange material or can be attached physically to the matrix as very small, chemically functionalized latex particles. The composite ion exchangers have much lower exchange capacity than the ion-exchange resins, but their hydrodynamic and mass transfer properties are much more favorable for rapid, high-performance chromatographic separations.

6. Ion exchange papers and layers. For ion-exchange paper chromatography, papers are impregnated with ion-exchange reagents, or finely distributed ion-exchange resin powder is embedded into the paper, or the paper itself is prepared from cellulose ion exchanger. For ion-exchange thin-layer chromatography, the sheets are usually prepared from ion-exchange resin powder of very low particle size and fixed by an inert adhesive material.

7. Ion-exchange membranes. Ion-exchange membranes are films or thin (0.1–0.6 mm) ion-exchange sheets with appropriate mechanical properties, and with proper porosity and low electrical resistance.

8. Liquid ion exchangers. Liquid ion exchangers are solutions of high molecular mass organic acids (cation exchangers) or bases (anion exchangers) which are sparingly soluble in water but readily soluble in less polar organic solvents and by which ions can be extracted from aqueous solutions.

9. Monolithic ion exchangers. A monolithic ion exchanger is formed from a continuous bed of silica or polymer (rather than discrete particles) in which interconnecting and cross-linked strands of material form a uniform, porous structure. This structure is then functionalized to produce anion or cation exchangers. Monolithic materials have low flow resistance and can therefore be operated at high flow rates.

## The Properties of Solid Ion Exchangers

The physical and chemical properties of solid ion exchangers are crucial to their characterization. Of the physical properties, color and density are the most important. For the granular products, particle size, particle size distribution, the shape of the particles, the bulk density, porosity, compressibility, mechanical stability, and the volume change caused by acidification or alkalization are important. For high-performance chromatographic separations, uniformity, regular spherical form, low compressibility, and low volume change of the particles on solvation are important. For the characterization of the ion-exchange membranes, the thickness and resistance against pressure change are also guiding properties.

The most important data for chemical characteristics are as follows:

- the ion-exchange capacity (referred to unit volume or mass);
- the nature of the functional groups;
- the water uptake;
- the structural porosity and rigidity of the matrix; and
- the chemical stability (against acidic/alkaline solutions as well as against oxidants and reductants; against radiation induced decomposition, etc.).

The ‘capacity’ of the ion exchanger expresses the amount of exchangeable singly charged ions either per unit mass or per unit volume. The determination of the capacity is usually carried out by acidimetric titration. For the chelating resins, the capacity may be determined by the uptake of copper(II) ions referred to unit mass or volume.

The affinities of the exchangeable ions to the fixed sites depend highly on the ‘nature of the functional groups’. The ratio of the adsorption strength of similar ions gives the selectivity of the ion exchangers.

As the ion exchange occurring in aqueous solutions is always accompanied with the transport of water molecules, the ‘water uptake’ is an important feature of ion exchangers. The inner porosity, the number of available exchange sites for ions of higher size, and the exchange rate of ions at the gel type ion-exchange resins depend strongly on the water content and swelling properties of the resin. With the so-called macroporous resins, the extent of swelling is lower due to their more rigid structure.

Inorganic ion exchangers exhibit a rigid network in which the number of available sites depends strongly on the diameter of the inner channels and on the size of the hydrated or less hydrated counterions.

For the long-term use of ion exchangers, their ‘chemical stability’ is an important characteristic which means that during the repeated depletion–regeneration cycles they should preserve their exchange capacities, without degradation of the mechanical and physical properties and without releasing any soluble organic compounds into the contacting solutions. For nuclear purposes, stability against radiation is also an important characteristic.

## Ion-Exchange Equilibria

The exchange process of two cations (or anions) A and B taking place between two immiscible phases can be described by the following equation (the possible transfer of solvent molecules is neglected):

where  $z_A$  and  $z_B$  denote the charges on the two ions, respectively. The fraction of the ion exchanger equivalent to one singly charged counter ion is denoted by  $X$ . At equilibrium

$$K_{A/B}^T = \frac{(\bar{a}_B)^{z_A} (a_A)^{z_B}}{(\bar{a}_A)^{z_B} (a_B)^{z_A}} \quad [1]$$

where  $\bar{a}$  and  $a$  denote the activities in the ion exchanger and in the contacting liquid phase, respectively.  $K_{B/A}^T$  is the thermodynamic equilibrium constant. In the calculation and also in the prediction of thermodynamic equilibrium constant values, difficulties arise from the fact that the activities inside the ion exchanger phase are not measurable, and the values of the mass action ratio expressed in terms of concentrations ( $K_{B/A}^c$ , see eqn [2]) usually depend on the mole ratio of the ions inside the ion exchanger phase:

$$K_{B/A}^c = \frac{[B]_R^{z_A} [A]_{aq}^{z_B}}{[A]_R^{z_B} [B]_{aq}^{z_A}} \quad [2]$$

The mass action ratio can be expressed also in terms of equivalent fractions, denoted by  $\bar{x}$  and  $x$  in the ion exchanger and in the contacting liquid phase, respectively:

$$K_{B/A}^x = \frac{(\bar{x}_B)^{z_A} (x_A)^{z_B}}{(\bar{x}_A)^{z_B} (x_B)^{z_A}} \quad [3]$$

where

$$\bar{x}_B = \frac{z_B [B]_R}{z_A [A]_R + z_B [B]_R} \quad [4]$$

$$\bar{x}_A = \frac{z_A [A]_R}{z_A [A]_R + z_B [B]_R} \quad [5]$$

$$x_B = \frac{z_B[B]_{aq}}{z_A[A]_{aq} + z_B[B]_{aq}} \quad [6]$$

$$x_A = \frac{z_A[A]_{aq}}{z_A[A]_{aq} + z_B[B]_{aq}} \quad [7]$$

The 'selectivity ratio' (separation factor) of the two ions, independently of their charge, is as follows:

$$\alpha_{B/A} = \frac{[B]_R [A]_{aq}}{[B]_{aq} [A]_R} = \frac{D_B}{D_A} \quad [8]$$

where  $D_B$  and  $D_A$  are the distribution ratios of ion B and ion A (see later). The larger the value of  $\alpha_{B/A}$ , the larger the selectivity of the ion exchanger for the preference of B ions over A ions. The relationship between  $K^T$  and  $K^C$  is as follows:

$$K_{B/A}^C \frac{(\bar{f}_B)^{z_A}}{(\bar{f}_A)^{z_B}} \frac{(f_A)^{z_B}}{(f_B)^{z_A}} = K_{B/A}^T \quad [9]$$

$\bar{f}_A, \bar{f}_B$  and  $f_A, f_B$  are the activity coefficients for the A, B ions in the ion exchanger and in the liquid phase, respectively. The relation between  $K^x$  and  $K^C$  is

$$K_{B/A}^x = K_{B/A}^C \frac{Q^{z_B}}{Q^{z_A}} \frac{C^{z_A}}{C^{z_B}} \quad [10]$$

$Q (= z_A[A]_R + z_B[B]_R)$  is the total concentration in the ion exchanger,  $C (= z_A[A]_{aq} + z_B[B]_{aq})$  is the total concentration in the contacting liquid phase expressed in terms of equivalents per volume unit and assuming a binary mixture. The subscripts R and aq refer to the exchanger and aqueous phase, respectively:

$$K_{B/A}^x = \alpha_{B/A} \left( \frac{x_A}{\bar{x}_A} \right)^{z_B-1} \left( \frac{\bar{x}_B}{x_B} \right)^{z_A-1} \quad [11]$$

If  $z_A = z_B$ , the relation is very simple:

$$K_{B/A}^C = K_{B/A}^x = \alpha_{B/A} \quad [12]$$

and the thermodynamic equilibrium constant can be calculated formally from the following relation if  $K_{B/A}^C$  values are known at various  $\bar{x}_B$ :

$$\ln K_{B/A}^T = \int_0^1 \left[ \ln K_{B/A}^C + \ln \frac{(f_A)^{z_B}}{(\bar{f}_B)^{z_B}} \right] d\bar{x}_B \quad [13]$$

In analytical chemistry, mainly the  $K_{B/A}^C$  and  $\alpha_{B/A}$  values are used for informatory calculations. The hydrogen ion is normally used as a reference for cations and the chloride ion for anions. Both  $K^C$  and  $\alpha$  values depend not only on the nature of the exchanging ions, but also on the nature of the ion

exchanger. As reference resin, Dowex  $50 \times 8$  is usually proposed for cation and Dowex  $1 \times 8$  for anion exchangers. Many attempts have been made to assess the selectivity of ion exchangers, and to explain factors influencing it. The main factors include the charge of the ion being exchanged (the 'electroselectivity effect'), the size of the ion being exchanged, and the chemical nature and steric arrangement of the functional group on the resin.

**Distribution ratio.** The distribution of an ionic species between the ion exchanger and the contacting phase is an important term in ion-exchange chromatography, because the migration rate of the ion on the chromatographic column and hence the position of the peak of the component in the chromatogram is controlled by the distribution ratio.

For a metal ion,  $M^{2+}$ ,

$$D_M = \frac{[M^{2+}]_R}{[M^{2+}]_{aq}} \quad [14]$$

The distribution ratio depends on the concentration of the competing ion in the electrolyte,  $E^+ Y^-$  (e.g., NaCl or HCl):

$$K_{M/E}^C = \frac{[M^{2+}]_R [E^+]_{aq}^2}{[M^{2+}]_{aq} [E^+]_R^2} \quad [15]$$

$$D_M = \frac{[M^{2+}]_R}{[M^{2+}]_{aq}} = K_{M/E}^C \frac{[E^+]_R^2}{[E^+]_{aq}^2} \quad [16]$$

If the  $M^{2+}$  metal ion is present in low concentration and the  $E^+$  'eluent' ion in medium concentration, the resin is practically in E-ion form and  $[E^+]_R$  is very close to  $Q$  (capacity of the resin), and  $K_{M/E}^C$  can be regarded as constant:

$$D_M = K_{M/E}^C Q^2 [E^+]_{aq}^2 \quad [17]$$

or in logarithmic form:

$$\log D_M = \log K_{M/E}^C + 2 \log Q - 2 \log [E^+] \quad [18]$$

There is a linear relation between the logarithm of the distribution ratio of the metal ion and the logarithm of the concentration of the competing eluent ion. The slope of the line corresponds to the ratio of the charges on the two ions (2/1). The distribution ratio of multicharged ions increases steeply with decreasing concentration of the singly charged eluent ion. It is interesting to note that the equation is valid not only in the case if  $Q$  is constant (i.e., the same ion exchanger is used) but also in the case if the concentration of the eluent is constant but the capacity of the ion exchanger is changing.

The  $D_M$  value of the metal ion can be influenced not only by the change of the eluent ion concentration but also by changing the actual value of the ion-exchange concentration constant. By using complex-forming agents, which form complexes of zero or of opposite charge with the metal ion, a conditional ion exchanger constant can be computed, which is of lower value than that of the original one. If a complex-forming agent,  $H_2L$ , is added to the solution, which forms complexes according to the equations

and the protonation of the ligand takes place according to the reactions

the conditional constant for the  $M^{2+}/E^+$  ion-exchange will be

$$K'_{M/E} = \frac{K_{M/E}^c}{\alpha_{M(L)}} \quad [19]$$

where

$$\alpha_{M(L)} = 1 + \frac{\beta_1 C_L}{\alpha_{L(H)}} + \frac{\beta_2 C_L^2}{\alpha_{L(H)}^2} \quad [20]$$

$$\alpha_{L(H)} = 1 + [H^+]K_1 + [H^+]^2K_1K_2 \quad [21]$$

If the pH, and the analytical concentration of the ligand,  $C_L$ , and  $[E^+]$  are known, the conditional constant value using eqn [19] and the conditional distribution ratio can be calculated too.

Similar calculations can be carried out for planning separations of metal ions, or of organic acids etc. using either solid or liquid ion exchangers, if the ion-exchange concentration constants, the corresponding protonation and complex formation constants are known.

Beside the ion-exchange process, 'absorption of electrolytes' also takes place if the ion exchanger is in contact with electrolyte solutions. The extent of the invasion of the ions depends on the concentration of the electrolyte in the solution and on the density of the ionic sites in the ion exchanger phase. The distribution of the electrolyte between the two phases is governed by Donnan equilibrium, and is significant only in solutions of higher than  $0.1 \text{ mol l}^{-1}$  concentration. At lower concentration the electrolyte is 'excluded' from the ion exchanger phase. For a single-single charge electrolyte of composition EY,

the concentration of  $Y^-$  in the ion exchanger phase can be estimated from the following equation:

$$[EY]_{aq}^2 = [Y^-]_R Q + [Y^-]_R^2 \quad [22]$$

The second term on the right-hand side can be neglected, and eqn [22] is simplified:

$$[Y^-]_R = \frac{[EY]_{aq}^2}{Q} \quad [23]$$

The ion-exclusion phenomenon is used in 'ion-exclusion chromatography' for separation of ions of different characters or charges.

Absorption of nonelectrolytes can take place from solution. The extent of the absorption depends on the matrix properties of the ion exchanger and on the electrolyte concentration of the liquid phase. The phenomenon is used for separation of nonelectrolytes and weak electrolytes by 'salting out chromatography'.

## Ion-Exchange Kinetics

As a general rule, the rate of ion-exchange processes is controlled by the diffusion of the exchanging ions. In a few cases the exchange rate is influenced by slow chemical reactions.

The rate controlling steps for solid ion exchangers are in general

- transport of the counterions across a thin liquid film (Nernst film) covering the surface of the ion exchanger and
- diffusion of the ions inside the solid ion exchanger phase.

In the mass transfer kinetics of the liquid-liquid ion exchanger processes, the contacting surface area and also the diffusion rate of the ions in the liquid phases are the controlling factors. The process can be highly accelerated by agitation.

For solid ion exchangers, considering spherical particles and for the simple ion exchange of isotopic species, if the process is controlled only by the diffusion of the ions in the thin film solution phase the fractional attainment of equilibrium as a function of time  $t$  can be expressed as follows:

$$F = 1 - e^{-(3dc/r\delta Q)t} \quad [24]$$

where  $d$  and  $c$  are the diffusion coefficient and concentration of the ion in the solution phase,  $r$  is the radius of the ion exchanger solid particle,  $\delta$  is the thickness of the liquid film, which can be influenced by agitation, and  $Q$  is the capacity of the ion exchanger. The half time (until  $F=0.5$ ) of the process is given by

$$t_{1/2} = 0.023r\delta d \frac{Q}{c} \quad [25]$$

For a reaction that is controlled solely by diffusion within the solid particle, the equation is

$$F = 1 - \frac{6}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{n^2} e^{-(\bar{d}\pi^2 n^2 / r^2)t} \quad [26]$$

where  $\bar{d}$  is the diffusion coefficient of the ion in the ion exchanger phase. The half time

$$t_{1/2} = 0.03r^2 / \bar{d} \quad [27]$$

depends only on the particle size and diffusion coefficient but not on the concentration.

Since the diffusion coefficients of simple ions in aqueous solutions at room temperature are  $\sim 10^{-5} \text{ cm}^2 \text{ s}^{-1}$ , while the diffusion coefficients inside the usual ion exchanger resins are in the range of  $10^{-9} - 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ , film diffusion is rate controlling only at very small particle size ( $10 \mu\text{m}$ ) and at low concentration. High concentration, large particle size, compact ion exchanger phase (strongly cross-linked polymer), and less mobile, large ions favor inner diffusion control.

## Application Techniques

Ion-exchange processes using solid ion exchangers are usually carried out either by a batch or column technique.

Since in the batch procedure the ion exchange comes to equilibrium, quantitative exchange of ions from a solution can be obtained only in the case if the exchange reaction is highly favored ( $K_{B/A}^x$  is high) or multicharged ions are absorbed from singly charged ion-containing solution of low concentration, and the ion exchanger is in a fairly large excess.

Using fixed bed ion-exchange column techniques, the quantitative exchange of ions can also be attained in those cases where the selectivity conditions are not very favorable. In these cases the length of the column and flow rate must be chosen properly.

## Applications

Applications of the *solid ion exchangers* in the analytical laboratory can be grouped into the following classes:

1. procedures based on the total ion-exchange principle,
2. chromatographic separations, and
3. use of ion exchangers as carriers.

For the procedures belonging to class 1, mainly column techniques, but in a few cases batch techniques also, can be used.

In 'inorganic analysis' the most important applications are as follows:

- titrimetric determination of the salt content of solutions, by transforming them either into acid or base;
- preparation of standard solution of acids and bases (e.g., preparation of carbonate-free alkali hydroxide solution);
- dissolution of weakly soluble salts (like gypsum);
- removal of interfering ions: either cations, or anions, or both; and
- enrichment of ions of low concentration; collection of metal ion impurities from large volumes of drinks or from natural waters. The adsorbed metal ions can be eluted thereafter with a small volume of a suitable electrolyte solution for subsequent determination. For selective adsorption of certain metal ions, the presence of chelate-forming functional groups can also be useful.

In quantitative analysis based mainly on column chromatographic techniques, elution methods are preferred. The displacement chromatographic separations are useful for preparative purposes. The chromatographic procedures are useful for separation of metal ions from each other using cation exchange column or in their anionic complex ion form using an anion exchanger column. For the separation of ions of nonmetallic elements ( $\text{Cl}^-$ ,  $\text{Br}^-$ ,  $\text{HPO}_4^{2-}$ , etc.), an anion exchanger column is used.

For the detection of the separated ions, spectrophotometric and other spectroscopic detection methods are used.

If the distribution ratio of the analyte is fairly high ( $D > 100$ ), but that of the accompanying ions are low, separation with selective sorption (solid phase extraction) can be achieved.

Ion-exchange resins are useful as carriers for storing reagents or indicators, and to facilitate their use in laboratory work.

In 'organic analysis', the procedures based on total ion exchange are used for transformation of salts to acids or to bases; for removal of electrolytes from the solution of nonionic compounds; for isolation and separation of ionic or ionizable compounds from interfering substances; and group separation of components of a mixture containing acidic, basic, and less polar components.

Using chromatographic techniques, mixtures of acids, amines, aldehydes, ketones, amino acids, sugars etc. can be analyzed. If salting out and ion-exclusion chromatographic techniques are included, quite a wide range of organic compounds can be separated and determined. By the use of dextran-based packing

materials, ionizable bioactive compounds of higher molar mass can be analyzed chromatographically.

In organic analysis, the ion exchangers can be used as carriers for preparation of solid reagents (e.g., diazo reagents or enzymes).

### Liquid Ion Exchangers

Liquid ion exchangers are useful for extraction of metal ions, free acids, or bases from aqueous solutions. The collected ions can be back-extracted using an electrolyte of proper composition for the determination after the separation of the phases.

### Ion-Exchange Membranes

Ion-exchange membranes can be used as electrodes for electrometric titration of the salt content of water, or in electrodialysis cells for separation of ions of different charge or of different mobility.

The ion-exchange sheets or papers containing ion-exchange groups (or being impregnated) can be used for separation of inorganic and organic ions or ionizable compounds using a buffer solution as eluent and using established thin layer or paper chromatographic techniques.

Columns filled with resins containing functional groups with oxidizing–reducing properties can be

used as columns, for the quantitative oxidation or reduction of certain components of an aqueous solution (e.g., reduction of iron(III) traces to iron(II) using Variamine Blue reductor).

### Introduction

The first evidence for ion exchange was found in the middle of the 19th century in the field of agricultural chemistry. In the beginning most of the investigations were carried out on clays and minerals and this led later to the introduction of zeolites as an ion exchange material. Folin and Bell introduced the first analytical application of ion exchange in 1909 in a method for the determination of ammonia in urine. In the earlier studies of the ion exchange equilibrium, the obtained results were considered from a pure empirical point of view. In 1928, the Donnan model was introduced as a theoretical model by the Swedish agricultural chemist S. Mattsson. However, it was not until the end of the 1940s that this model was generally accepted and became a starting point for the more elaborate models that were developed in the 1950s.

It is important that the nomenclature is clear and in this article the following is used: the volume of the column that is filled up with the ion exchange material and the liquid phase is divided into the solid phase, the resin phase, and the electrolyte phase. The solid phase is the part of the column to which the liquid cannot penetrate. The resin phase is the part of the column to which the liquid can penetrate but is stagnant in a chromatographic process. For a porous ion exchange material this phase mainly consists of the pore volume. The external electrolyte phase is the part of the column that is filled by the electrolyte and at the same time can be associated with a flow velocity in a chromatographic process.

The charges that are bound to the resin phase are called the fixed (resin) charges and they are the reference point for the nomenclature of the other ions in the ion exchange system. The ions in the electrolyte solution, which have a sign of charge that is opposite to the fixed resin charges, are called the counterions. Analogously, the charges that have the same sign are called the co-ions.

### Introduction

The first evidence for ion exchange was found in the middle of the 19th century in the field of agricultural chemistry. In the beginning most of the investigations were carried out on clays and minerals and this led later to the introduction of zeolites as an ion exchange material. Folin and Bell introduced the first analytical application of ion exchange in 1909 in a method for the determination of ammonia in urine. In the earlier studies of the ion exchange equilibrium, the obtained results were considered from a pure empirical point of view. In 1928, the Donnan model was introduced as a theoretical model by the Swedish agricultural chemist S. Mattsson. However, it was not until the end of the 1940s that this model was generally accepted and became a starting point for the more elaborate models that were developed in the 1950s.

It is important that the nomenclature is clear and in this article the following is used: the volume of the column that is filled up with the ion exchange material and the liquid phase is divided into the solid phase, the resin phase, and the electrolyte phase. The solid phase is the part of the column to which the liquid cannot penetrate. The resin phase is the part of the column to which the liquid can penetrate but is stagnant in a chromatographic process. For a porous ion exchange material this phase mainly consists of the pore volume. The external electrolyte phase is the part of the column that is filled by the electrolyte and at the same time can be associated with a flow velocity in a chromatographic process.

The charges that are bound to the resin phase are called the fixed (resin) charges and they are the reference point for the nomenclature of the other ions in the ion exchange system. The ions in the electrolyte solution, which have a sign of charge that is opposite to the fixed resin charges, are called the counterions. Analogously, the charges that have the same sign are called the co-ions.

This article focuses on the theoretical principles for solid particular ion exchangers and their use in analytical chemistry but many of the principles are, however, of more general character. In all ion exchange systems the electrostatic or Coulombic interaction between the electrolyte ions in the resin phase and the fixed resin charges is of great importance. To maintain electroneutrality, the fixed resin charges have counterions associated to it and their distribution in the resin phase is mainly the result of a balance between three effects: (1) electrostatic attraction to the fixed resin charges; (2) the smearing out effect of the thermal motion (i.e., the entropy); and (3) the way the counterions that are close to the fixed resin charges shield each other. It is important to recognize that (1) due to the thermal motion the counterions are not connected to the fixed resin charges as a 1:1 complex but as a diffuse layer close to the fixed charges and (2) there are co-ions present in the diffuse layer. The fixed charges together with the diffuse layer of ions form the so-called diffuse double layer. Since the fixed charges and the ions in the diffuse layer are separated in space, a difference in the electrostatic potential between a point in the diffuse double layer and a point in the bulk electrolyte solution is created. An important aspect of the electrostatic interaction is that it is long ranged, which contrasts to, e.g., the van der Waals interaction, implying that the presence of an ion at a given point simultaneously affects the energy of many ions, not only those that are in its closest vicinity.

The electrostatic potential difference between a point in the resin phase and the external electrolyte phase mainly determines the general properties of an ion exchanger. There is a general theory that was developed by R.A. Marcus for polyelectrolytes that may be used to connect the potential difference to the activity coefficient of an ion, and is therefore discussed in more detail. This theory is a useful starting point with which the more specific theories, which have been put forward in ion exchange, can be compared. In traditional ion exchange theory, the Donnan potential model is generally used to derive useful relations between different quantities. A comparison between the Donnan model and the more general theory is made. In more recent years, several theories based on the electrical double layer concept have been presented to explain ion exchange data and these are also shortly discussed.

Differences in electrostatic potential between the external electrolyte phase and the resin phase cannot explain selectivity differences between counterions of the same net charge. Much work has been done in many areas of chemistry to investigate the cause of selectivity and no well-established theoretical model exists. Some general empirical results are presented here as well as a simple theoretical model.

## Theory

Consider a resin phase with fixed charged groups and which is in equilibrium with an external electrolyte solution containing an ion  $B_B^z$ . The thermodynamic condition for equilibrium for  $B_B^z$  between the external solution and the resin phase is determined by the equivalence of the chemical potential in the two phases. Although the chemical potential for a single charged species is not a measurable quantity, the following equation can be used to theoretically describe the equilibrium condition:

$$\begin{aligned}\mu_{B,E}^0 + RT \ln c_{B,E} \gamma_{B,E} \\ = \mu_{B,R}^0 + RT \ln c_{B,R} \gamma_{B,R}\end{aligned}\quad [1]$$

where  $\mu_{B,E}^0$  and  $\mu_{B,R}^0$  are the standard chemical potentials for  $B_B^z$  in the external solution and in the resin phase, respectively.  $c_{B,E}$  and  $c_{B,R}$  are the concentrations of  $B_B^z$  in the external solution and its mean concentration in the resin phase, respectively. The activity coefficients,  $\gamma_{B,E}$  and  $\gamma_{B,R}$  are introduced in order to take account of the, usually strong, deviations from classical laws that are exhibited in ion exchange systems.  $R$  is the Avogadro constant and  $T$  the temperature. Assuming that the standard chemical potential is equal in the two phases, i.e.,  $\mu_{B,E}^0 = \mu_{B,R}^0$ , eqn [1] can be rewritten as

$$\frac{\gamma_{B,R}}{\gamma_{B,E}} = \frac{c_{B,E}}{c_{B,R}}\quad [2]$$

Thus, the relative accumulation (depletion) of  $B_B^z$  in the resin phase, relative to the surrounding electrolyte solution, is determined by the corresponding ratio of activity coefficients. In eqn [2] the ratio of activity coefficients is introduced as a pure empirical quantity and to proceed from here a physical interpretation and its theoretical explanation is needed.

As explained above, the charges in the resin phase give rise to a difference in electrostatic potential between the external solution and the resin phase and also to electrostatic potential gradients within the resin phase. In the following discussion it is assumed that electrostatic effects are the only factors that contribute to changes in the activity coefficients.

From physics we know that the work needed to move a positive unit test charge between two points is proportional to the difference in electrostatic potential between these points. The expression for chemical equilibrium, eqn [1], is related to the energy for an ion in the external and resin phases, respectively. Therefore, a term for the electrostatic energy can be introduced in the expression for the chemical potential and the electrochemical potential is obtained. For a small ion  $B_B^z$ , the thermodynamic

condition for equilibrium between a point in the external solution and a point  $r$  in the resin phase is now determined by the equivalence of the electrochemical potential in the external solution and point  $r$ :

$$\mu_{B,E}^0 + RT \ln c_{B,E} = \mu_{B,R}^0(r) + RT \ln c_{B,R}(r) + z_B F \cdot \Delta\Psi(r) \quad [3]$$

where  $\Delta\Psi(r)$  is the difference in electrostatic potential between a point  $r$  in the resin phase and the external electrolyte phase and  $F$  is the Faraday constant. Assuming that the electrostatic potential is the only difference that  $B_B^z$  experiences between the two phases, the standard chemical potential is equal, i.e.,  $\mu_{B,E}^0 = \mu_{B,R}^0(r)$  and from eqn [3] the Boltzmann equation for the concentration of  $B_B^z$  in point  $r$  is obtained:

$$c_{B,R}(r) = c_{B,E} \cdot e^{\frac{-z_B F \cdot \Delta\Psi(r)}{RT}} \quad [4]$$

For a cation exchanger, which contains negatively charged surface groups  $\Delta\Psi(r)$  is negative and from eqn [4] it follows that when  $z_B$  is positive (negative) the concentration of  $B_B^z$  is higher (lower) in a point  $r$  in the resin phase than in the external electrolyte solution. In an anion exchanger the conditions are reversed, i.e., the electrostatic potential is positive giving higher (lower) concentrations of anions (cations) in the resin phase compared to the external solution.

The total amount of  $B_B^z$  in the resin phase is equal to its mean concentration,  $c_{B,R}$ , times the volume of the resin phase,  $V_R$ . According to eqn [4], this amount is equal to the integral of  $c_{B,R}(r)$  over the volume  $V_R$ , i.e.,

$$c_{B,R} \cdot V_R = \int_{V_R} c_{B,R}(r) dV_R = c_{B,E} \cdot \int_{V_R} e^{\frac{-z_B F \cdot \Delta\Psi(r)}{RT}} dV_R \quad [5]$$

By comparing eqns [2] and [5], a physical interpretation of the ratio of activity coefficients is obtained:

$$\frac{\gamma_{B,R}}{\gamma_{B,E}} = \frac{c_{B,E}}{c_{B,R}} = \frac{V_R}{\int_{V_R} e^{\frac{-z_B F \cdot \Delta\Psi(r)}{RT}} dV_R} \quad [6]$$

## Ion Exchange Equilibrium

### General Considerations

Consider a cation exchanger that is in equilibrium with an electrolyte solution containing two identically charged cations, A and B, and a common anion. The ion exchange equilibrium between cations A and

B is usually written as

where  $A_E$  and  $A_R$  are the ion A in the external solution and resin phase, respectively, and  $B_E$  and  $B_R$  those corresponding to ion B. Equilibrium (7) gives the following thermodynamic equilibrium constant:

$$K_{A,B}^T = \frac{c_{B,E} \gamma_{B,E} \cdot c_{A,R} \gamma_{A,R}}{c_{B,R} \gamma_{B,R} \cdot c_{A,E} \gamma_{A,E}} \quad [8]$$

The selectivity coefficient for ion exchange equilibrium is obtained when the mass action law without activity coefficients is used, i.e., for the equilibrium in eqn [7] the coefficient is

$$K_{A,B}^S = \frac{c_{B,E} \cdot c_{A,R}}{c_{B,R} \cdot c_{A,E}} \quad [9]$$

In ion exchange chromatography, the retention of an analyte ion A is related to its distribution ratio  $D_A$ , defined as

$$D_A = \frac{c_{A,R}}{c_{A,E}} \quad [10]$$

and by combining eqns [8] and [10], we find that

$$D_A = \frac{c_{B,R} \gamma_{B,R} \cdot \gamma_{A,E}}{c_{B,E} \gamma_{B,E} \cdot \gamma_{A,R}} \cdot K_{A,B}^T \quad [11]$$

Equation [11] shows that the distribution constant for A depends on the ratio of activity coefficients and the concentration of the counterion B in the resin and external phases, respectively. When  $c_{B,E}$  increases, the main effect is a decrease in the electrostatic interaction to the fixed charges in the resin phase, which in turn affects the individual activity coefficients. It is therefore interesting to evaluate the ratio of activity coefficients in eqn [11]. Since eqn [6] applies individually to all ions in the electrolyte solution that are in equilibrium with the resin phase, a relation between  $K_{A,B}^T$ ,  $K_{A,B}^S$ , and  $D_A$  can be found.

For the equilibrium in eqn [7], we have that  $z_A = z_B$  and we find that the integrals on the right-hand side of eqn [6] are equal for the two ions and we obtain

$$K_{A,B}^T = \frac{c_{B,E} \cdot c_{A,R}}{c_{B,R} \cdot c_{A,E}} = K_{A,B}^S = 1 \quad \text{or} \quad D_A = \frac{c_{B,E}}{c_{B,R}} \quad [12]$$

Equation [12] shows that when only electrostatic effects are operating, the relative concentration of equally charged ions in the resin phase is the same as in the external electrolyte solution. In this particular case, the selectivity coefficient and the thermodynamic equilibrium constant are equal.

A more complicated case arises when the equilibrium simultaneously involves a monocharged cation

( $z_B = 1$ ) and a dicharged cation ( $z_A = 2$ ). The ion exchange equilibrium is now written as

and the corresponding equilibrium constant is

$$K_{A,B}^T = \frac{c_{B,E}^2 \gamma_{B,E}^2 \cdot c_{A,R} \gamma_{A,R}}{c_{B,R}^2 \gamma_{B,R}^2 \cdot c_{A,E} \gamma_{A,E}} \quad [14]$$

By using eqn [6], eqn [14] can be written as

$$K_{A,B}^T = \frac{c_{B,E}^2 \left( \int_{V_R} e^{\frac{-F \cdot \Delta \Psi(r)}{RT}} dV_R \right)^2 \cdot c_{A,R} V_R}{c_{B,R}^2 V_R^2 \cdot c_{A,E} \int_{V_R} e^{\frac{-2F \cdot \Delta \Psi(r)}{RT}} dV_R} \quad [15]$$

The exact numerical value for  $K_{A,B}^T$ , thus, depends on the ratio of the integrals in eqn [15], a value that is not easily accessible. However, in mathematics we have Schwarz's inequality, which for this particular case gives the following relation:

$$\frac{\gamma_{B,E}^2 \cdot \gamma_{A,R}}{\gamma_{B,R}^2 \cdot \gamma_{A,E}} = \frac{\left( \int_{V_R} e^{\frac{-F \cdot \Delta \Psi(r)}{RT}} dV_R \right)^2 \cdot V_R}{V_R^2 \cdot \int_{V_R} e^{\frac{-2F \cdot \Delta \Psi(r)}{RT}} dV_R} \leq 1 \quad [16]$$

and that

$$\begin{aligned} K_{A,B}^T &= \frac{c_{B,E}^2 \gamma_{B,E}^2 \cdot c_{A,R} \gamma_{A,R}}{c_{B,R}^2 \gamma_{B,R}^2 \cdot c_{A,E} \gamma_{A,E}} \\ &\leq \frac{c_{B,E}^2 \cdot c_{A,R}}{c_{B,R}^2 \cdot c_{A,E}} = K_{A,B}^s \end{aligned} \quad [17]$$

Equation [17] shows that the selectivity coefficient in this case is always greater than the thermodynamic equilibrium constant. This implies that there will be an accumulation of dicharged ions in the resin phase compared to what is expected from a simple mass action approach.

A literal interpretation of the equilibrium in [13] would be that, in order to keep electroneutrality in the resin phase, the sorption of a dicharged ion must be accompanied by desorption of two monocharged ions. At a first glance, eqn [17], therefore, seems to violate the principle of electroneutrality in the resin phase. However, the concentration for all types of ions in the external electrolyte is in equilibrium with the resin phase. In this particular case, this implies that the sorption of a dicharged ion will to a certain extent be accompanied by a sorption of the co-ion to the resin phase so that electroneutrality in the resin phase is maintained.

The strength of the above result is that the ratio of activity coefficients, eqn [6], is based on a minimum

of assumptions. It is independent of the geometry of the resin phase and also applicable to all ions in an ion exchange system. However, a numerical evaluation of the integrals requires models for  $\Delta \Psi(r)$  at various compositions and for the geometry under consideration. In the following paragraphs two models will be discussed.

### The Donnan Model

In the Donnan model, it is assumed that the difference in electrostatic potential between the external electrolyte solution and the resin phase is constant and the same at all points in the resin phase, i.e.,  $\Delta \Psi(r) = \Psi_D$  for all  $r$ . When this assumption is applied to eqn [6], eqn [18] is obtained:

$$\frac{\gamma_{B,R}}{\gamma_{B,E}} = \frac{c_{B,E}}{c_{B,R}} = \frac{V_R}{\int_{V_R} e^{\frac{-z_B F \cdot \Delta \Psi_D}{RT}} dV_R} = \frac{1}{e^{\frac{-z_B F \cdot \Delta \Psi_D}{RT}}} \quad [18]$$

It is obvious that the Donnan model, when applied to an ion exchange equilibrium between equally charged ions, will give the same result as previously, eqn [12]. For the more complicated equilibrium in [13], the following is obtained:

$$\begin{aligned} K_{A,B}^T &= \frac{c_{B,E}^2 \left( \int_{V_R} e^{\frac{-F \cdot \Psi_D}{RT}} dV_R \right)^2 \cdot c_{A,R} V_R}{c_{B,R}^2 V_R^2 \cdot c_{A,E} \int_{V_R} e^{\frac{-2F \cdot \Psi_D}{RT}} dV_R} \\ &= \frac{c_{B,E}^2 \left( e^{\frac{-F \cdot \Psi_D}{RT}} \right)^2 \cdot c_{A,R}}{c_{B,R}^2 \cdot c_{A,E} \cdot e^{\frac{-2F \cdot \Psi_D}{RT}}} \\ &= \frac{c_{B,E}^2 \cdot c_{A,R}}{c_{B,R}^2 \cdot c_{A,E}} = K_{A,B}^s \end{aligned} \quad [19]$$

Thus, the assumptions behind the Donnan model give as a result an equilibrium distribution that is the same as from a straightforward use of the mass action law. This is the reason why the mass action law frequently is used to describe an ion exchange process. It is clear that the result from the Donnan model is limited to the case where the electrostatic potential within the resin phase is constant, or nearly so.

### Double Layer Models

In the general case the electrostatic potential is not constant but varies within the resin phase. To be able to calculate the electrostatic potential at a point as a function of the ionic strength, the geometry and the charge density of the system must be specified. The electrostatic potential at a point is usually obtained by solving the Poisson–Boltzmann equation, which is a combination of the Boltzmann equation, eqn [4], with the Poisson equation from electrostatics. The

latter equation relates the change in electric field strength, i.e., the derivative of the electrostatic potential at a point, to the charge density at that point:

$$\nabla^2 \Psi = -\frac{\rho}{\epsilon_0 \epsilon_r} \quad (\text{Poisson equation}) \quad [20]$$

where  $\rho$  is the charge density,  $\epsilon_0$  the permittivity of vacuum, and  $\epsilon_r$  the dielectric constant of the medium. The charge density at a point is the difference between the number of positive and negative charges (ions) at that point, i.e.,

$$\rho = F \cdot \sum_i z_i c_i \quad [21]$$

where the summation is taken over all ions  $i$  present. By combining eqns [20] and [21], the Poisson–Boltzmann equation is obtained. This equation is the basis for our understanding of, e.g., the behavior of electrolyte solutions in contact with charged surfaces as well as many other physical phenomena. When solved for a particular geometry it gives the electrostatic potential, the concentration of the different ions, and the electric field at any point. Then, in principle, it is possible to calculate the ratio of activity coefficients in eqn [6]. However, for complicated geometries this is rather difficult to perform and has not been applied to resins used in ion exchange. For some simple cases exact solutions to the Poisson–Boltzmann equation exist, one such case is a planar charged surface in contact with an electrolyte solution containing a  $z$ - $z$  electrolyte, the Gouy–Chapman equation. This equation expresses the electrostatic potential at the surface and at any distance from the surface, as a function of the surface charge density and the ionic strength of the electrolyte solution. The exact equations can be found in most textbooks in surface and colloid chemistry.

Figure 1A shows the electrostatic potential calculated from the Gouy–Chapman equation for three different concentrations of monovalent salt in a water solution, as a function of the distance from a negatively charged planar surface. Figure 1B shows the concentration profile of the monovalent counterion corresponding to the three salt concentrations in Figure 1A. It is interesting to observe that the concentration at the surface is only  $\sim 20\%$  higher when going from 1 to 500  $\text{mol m}^{-3}$  in the electrolyte solution. The counterion concentration at the surface is therefore quite insensitive to changes in the salt concentration in the bulk electrolyte.

### Specific Interactions

In the Gouy–Chapman equation, the electrolyte ions are considered to be point charges that interact with

**Figure 1** (A) The electrostatic potential and (B) the counterion concentration as a function of distance from a negatively charged surface (surface charge density  $-0.1 \text{ C m}^{-2}$ ) according to the Gouy–Chapman theory, for three different concentrations of a 1:1 electrolyte (1, 100, and 500  $\text{mol m}^{-3}$ ). (Reprinted with permission from Ståhlberg J (1994) Retention models for ions in chromatography (review). *Analytical Chemistry* 66: 440; © American Chemical Society.)

smeared out surface charges by electrostatic interactions only. Although the pattern that emerges from this simple theory has been verified in numerous experiments, some modifications of it may be necessary

to make. When real ions interact with a charged surface, one must consider the possibility of specific interactions between the ion and the resin with its fixed charges. These interactions are usually referred to as the chemical part of the interaction and are short ranged, in contrast to the electrostatic interaction that is a long ranged interaction. The short ranged nature of the interaction implies that only ions that are close to the surface may interact chemically with the surface, while ions that are further away in the double layer do not. For an ion B that interacts chemically with the surface a mass action law is often used for describing the association

$$K_{\text{ch}} = \frac{[\text{B-S}]}{c_{\text{B}}(s) \cdot [\text{S}]} \quad [22]$$

where  $K_{\text{ch}}$  is the association constant for forming the B-S complex, (S) is the concentration of free surface groups to which B can bind.  $c_{\text{B}}(s)$  is the local concentration of B at the surface and can be calculated from eqn [4], i.e.,

$$c_{\text{B}}(s) = c_{\text{B,E}} \cdot e^{\frac{-z_{\text{B}}F \cdot \Psi(s)}{RT}} \quad [23]$$

where  $\Psi(s)$  is the electrostatic potential at the surface. In the physical chemistry of colloids and surfaces, much work has been done to find models that describe the adsorption of different ions to different kinds of charged surfaces. One problem is where to locate the plane of interaction between the counterions and the charged surface. Different models suggest different positions of the plane, depending on the geometrical properties of the surface. In the model above, it is assumed that the interaction takes place in the same plane as the surface charges.

An example of a system that has been extensively studied is the interaction between electrolyte ions and the molecularly smooth and impenetrable charged mercury surface. The theory developed for this system is the well-known Stern–Gouy–Chapman model that divides the interfacial region into three layers, see Figure 2. In this model, it is assumed that the size of the counterions hinders them from coming closer to the metal surface than a certain distance. The associated counterions are therefore located in a plane, the inner Helmholtz plane (IHP), separated from the solid surface and exposed to a potential  $\Psi_{\text{IHP}}$ . This creates a charge-free region confined between the surface and the IHP and a corresponding drop in the electrostatic potential from  $\Psi_0$  to  $\Psi_{\text{IHP}}$ . Ions situated at IHP are close enough to bind chemically and it is also assumed that there is room for a limited number of ions in this region, described as a

**Figure 2** A schematic representation of the electrostatic potential as a function of the distance from the surface according to the Stern–Gouy–Chapman model. Langmuir isotherm. In the model it is furthermore assumed that the Gouy–Chapman model holds for large distances from the surface and up to the outer Helmholtz plane (OHP) with the potential  $\Psi_{\text{OHP}}$ .

### Retention Models for Ion Exchange Chromatography of Small Ions

In analytical applications of ion exchange chromatography two aspects of retention are of main interest: (1) How does the retention factor vary with the concentration of eluent salt? (2) What factors determine the selectivity between different analyte ions? From a theoretical point of view, it is clear that with increasing concentration of electrolyte in the external solution, the magnitude of the electrostatic potential in the resin phase decreases. The reason is that the added electrolyte ions partly shield the charges bound to the resin phase. For analyte counterions this implies that their sorption to the resin phase decreases giving a lower retention factor.

In chromatography, the retention factor, or, equivalently, the capacity factor, is used to characterize the chromatographic equilibrium properties of an analyte. The retention factor of an analyte,  $k$ , is usually derived to be the product of the column phase ratio,  $V_{\text{R}}/V_{\text{E}}$ , and the distribution coefficient of the analyte between the stationary phase and eluent phase,  $c_{\text{A,R}}/c_{\text{A,E}}$ , eqn [24]:

$$k = \frac{V_{\text{R}}}{V_{\text{E}}} \cdot \frac{c_{\text{A,R}}}{c_{\text{A,E}}} = \frac{t_{\text{R}} - t_0}{t_0} \quad [24]$$

The retention factor is experimentally measured from the retention time (or volume) of the analyte,

$t_R$ , and the retention time (or volume) for a marker,  $t_0$ . A physical interpretation of the experimentally determined retention factor shows that it depends on a number of different assumptions. In the derivation of eqn [24] it is assumed that the marker used to determine the column dead volume,  $V_E$ , does not penetrate into the resin phase so that any part of  $V_R$  is not included into the value of  $V_E$ .

For equilibrium [11], the most used quantitative relation of  $k$  as a function of electrolyte salt concentration is based on the assumption of a Donnan potential in the resin phase, i.e., eqn [19] is assumed to be valid. It is also assumed that the concentration of co-ions to the surface charges is negligible in the resin phase so that  $c_{B,R}$  is equal to the concentration of surface charges in the resin phase,  $C_R$ . This value is therefore constant and independent of the concentration of  $c_{B,E}$  in the eluent phase. Combining eqn [19] with eqn [24] gives the following expression for the retention factor as a function of  $c_{B,E}$ :

$$k = \frac{V_R}{V_E} \cdot \frac{c_{A,R}}{c_{A,E}} = K_{A,B}^s \cdot \frac{c_{B,R}^2}{c_{B,E}^2} \cdot \frac{V_R}{V_E} \\ = K_{A,B}^s \cdot \frac{C_R^2}{c_{B,E}^2} \cdot \frac{V_R}{V_E} \quad [25]$$

In practice, ion exchange data are usually represented in a  $\log k$  versus  $\log c_{B,E}$  plot which for a divalent analyte eluted with a monovalent counterion have the form

$$\log k = \log K_{A,B}^s \cdot C_R^2 \cdot \frac{V_R}{V_E} - 2 \log c_{B,E} \quad [26]$$

The same type of arguments is applied to the more general case and the following expression is often used:

$$\log k = \log K - \frac{z_A}{z_B} \log c_{B,E} \quad [27]$$

where  $K$  is a system constant,  $z_A$  and  $z_B$  the charges of the analyte and the electrolyte counterion, respectively. Experimental data for mono- and discharged ions usually agree well with this equation, for higher charged ions the agreement is generally not very good.

### Selectivity

The discussion so far has been concerned with the role of the charge of the analyte and the electrolyte counterion on the equilibrium distribution of the analyte between the resin and external phase, respectively. It is clear that the distribution to the resin phase of a multivalent ion is higher than for a mono-charged ion, a phenomenon that is easy to understand from the previous discussion. There is therefore

selectivity for ions of higher charge, usually called electroselectivity. Selectivity differences are also found within the class of equally charged ions, which is the basis for their chromatographic separation. For a strong cation exchanger the following affinity sequence to the resin phase is usually found:

For a strong anion exchanger the sequence is often found to be

These sequences are not absolute but depend on the nature of the fixed resin charge and the type of resin. In general, the affinity increases with decreasing hydrated radius and increasing polarizability of the ion. The physical explanation to selectivity probably involves several mechanisms, many models have been proposed but no one model is generally accepted. The situation is analogous to the situation in colloid chemistry where the above series is similar to the Hofmeister series for coagulation. Both affinity series supports the idea that it is the ions that are located close to the surface and the fixed resin charges that is responsible for the selectivity. A simple approach, which has been used in colloid chemistry, is therefore to use the equilibrium constant in eqn [22] and ascribe a higher affinity to a higher value of this constant.

### Introduction

Ion chromatography (IC) is an analytical variant of traditional ion-exchange chromatography providing the advantages of better separation, efficiency of columns, and higher sensitivity. Besides ion-exchange chromatography, variants such as ion-interaction (or 'ion pair') and ion-exclusion chromatography are also associated with IC.

It is generally accepted that the beginning of IC was in 1975, when the principle of reduction or suppression of the background conductivity of a strong eluent in a second sequential suppressed column was offered. Simultaneously, ion exchangers of low capacity were proposed for better separation and detection in such dual-column modes. In suppressed IC, a significant improvement in the sensitivity of conductivity detection was achieved. Later, in 1979, nonsuppressed IC or single-column IC using weak eluents of low-conductivity and low-capacity ion-exchange columns was offered. IC developed intensively in the past decades and is now one of the basic methods of analytical chromatography, along with high-performance liquid chromatography and gas chromatography. According to data of the *Journal of Chromatography* (Further Reading section), more than 5400 papers on different aspects of IC were published during 1975–2002. Many of them were devoted to improvement of IC instrumentation.

### General Questions of Ion Chromatography Instrumentation

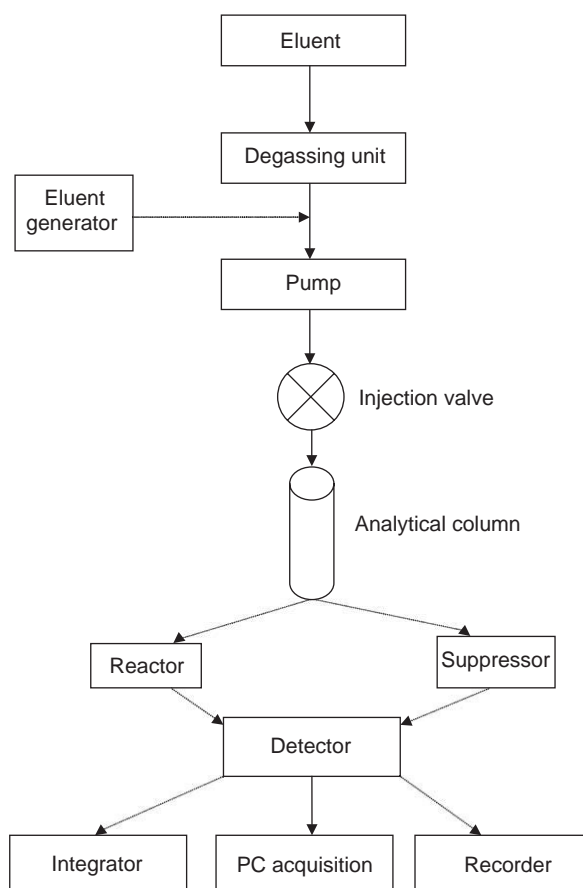

The first IC instruments appeared soon after the first publication about IC in 1977. At present, ~16–18 companies produce and sell laboratory equipment for IC totaling a sum of ~200 million dollars per year and automatic IC systems for industrial purposes totaling a sum of more than 10 million dollars. The wide application of IC for environmental control, foodstuff and drinks, in medicine, in energetics, in agrochemistry, and other areas is connected with the appearance of versatile instrumentation in the last few years. Different types of instruments ranging from small, portable, and personal systems to unattended industrial analytical systems have been developed.

**Scheme of an ion chromatograph** The scheme of a modern ion chromatograph is shown in Figure 1.

The typical ion chromatograph consists of an eluent generator or an eluent reservoir with degassing facilities; an eluent delivery system including an isocratic or a gradient high-pressure pump, sample pretreatment and injection system, which is either a manual valve or an autosampler; a separation column; a detection system, which includes modification of the effluent composition to achieve better selectivity or sensitivity; and a data acquisition system, which is mainly based on personal computers. The main feature of typical IC instrumentation is the so-called suppression system allowing the decrease of background conductivity of the effluent and providing better sensitivity for conductimetric detection.

### Evolution of Ion Chromatography Instrumentation

From the establishment of IC as an analytical technique, the evolution of IC instrumentation was directed toward improvements in separation efficiency

**Figure 1** Scheme of ion chromatograph.

associated with getting more chromatographic peaks in a shorter time, increase of sensitivity of conductivity detection and introduction of new detectors, improvement of accuracy in IC analysis, and miniaturization of instruments. The main steps in the evolution of IC systems are presented in Table 1.

## Detection by Electrical Conductivity

All ions carry electric charges; therefore, all solutions of ions conduct electricity. Electrical conductivity provides a general method for detecting ions in solution. All ions do not conduct equally well; some migrate faster in an electric field than others.

**Table 1** Some evolution steps of IC instrumentation

Evolution step	Effect
Gradient elution in addition to isocratic elution	Increased number of separated ions in one chromatographic run, decrease of analysis time
Introduction of metal-free pumps and liquid paths from nonmetallic materials (ceramics, plastic PEEK, sapphire, PTFE e.a.) in ion chromatograph	Improved accuracy of determination of metal ions and related ions, decreased corrosion of instruments
Use of multiple column switching valves, especially for sample pretreatment and in simultaneous separation of anions and cations	More versatile IC analysis of complex samples
Development of dual-flow IC systems	Simultaneous separation of anions and cations
Automated in-line filtration of sample to prevent fouling of chromatographic columns	Longer lifetime of chromatographic columns
Programmable loop selection based on 10-port injection valve	Optimization of analytical procedure for analysis of samples with widely ranging concentration of ions
Development of PC databases for control of chromatographs and treatment of results	Significant simplification in data treatment
Miniaturization of systems based on micro-packed and capillary columns	Possibility of analysis of microsamples, better compatibility with MS detectors
Development of reliable chip ion chromatographs	
Introduction of new types of detectors including PAD, ICP-MS, etc.	Expansion of application area of IC, in particular, in analysis of sugars, amino acids, biogenic amines, etc.
Simultaneous separation and detection of anions and cations	Possibility to obtain full information of ion composition of the sample
Constant improvement of suppressor systems	Increase of sensitivity of conductimetric detection as the basic detection method
Development of reagent-free IC system with electrochemical generator of eluent (see Figure 2)	Possibility to manipulate with concentration of the eluent through electronics
Introduction of monolithic columns for	Ultra-fast separation, in particular, separation of common anions for 15 s ( $\text{H}_2\text{PO}_4^-$ , $\text{Cl}^-$ , $\text{NO}_2^-$ , $\text{Br}^-$ , $\text{NO}_3^-$ , $\text{ClO}_3^-$ , $\text{I}^-$ , $\text{SO}_4^{2-}$ )

The conductance of a salt, AX, in dilute solution is the sum of the conductivities of the two ions:

$$\lambda_{\text{AX}} = \lambda_{\text{A}} + \lambda_{\text{X}}$$

The ions conduct independently and are free for electrostatic interaction, which can be neglected for our purposes. Table 2 lists some equivalent ionic conductances. These are the currents in amperes that would flow if a potential difference of 1 V were applied to a cell having two metallic plates, each  $1 \text{ cm}^2$  in area and placed 1 cm apart, with a solution between them that contained 1 g equiv of the ions in question in  $1 \text{ cm}^3$ . The unit of  $\lambda$ , therefore, is  $\Omega^{-1} \text{ cm}^2 \text{g-equiv}^{-1}$ . The reciprocal ohm,  $\Omega^{-1}$ , is commonly called the Siemens (S). The conductances of the dilute solutions used in IC are commonly in the range of  $\mu\text{S}$ .

When a solution of a salt, AX, is introduced at the head of a cation-exchange column into a flowing solution of BX, ions A enter the exchanger, move back and forth between the exchanger and the solution, and eventually come out in the effluent, taking the place of ions B. The concentration of ions X in the flowing solution remains constant, and therefore the sum of the concentrations of ions A and B must remain constant. A plot of these concentrations at the column exit, versus time, resembles the one shown in Figure 3. If the equivalent conductivities of ions A and B are equal, there is no change in the conductivity of the column effluent. If, however, ions B conduct better than ions A, the conductivity decreases as ions A emerge. This is the case when sodium ions are introduced into a flowing stream of hydrogen ions in a dilute acid. If ions A conduct better than ions B, the conductivity increases as ions A emerge. This is the case when calcium ions are displaced by an eluent containing the doubly charged ethylenediammonium cation, or, in anion exchange, when chloride or

**Figure 3** Concentrations and conductivities at column exit. (Reproduced from Walton HF (1987) *Ion-Exchange Chromatography*, ACS Audio Course C-93, p. 49. Washington, DC: American Chemical Society; © American Chemical Society.)

nitrate ions are displaced by an eluent of sodium benzoate.

The changes in concentration and conductivity shown schematically in Figure 3 take place against a high background conductivity of the eluent, BX, which is always present in excess. When high-capacity, gel-type resins are used the eluent concentrations are so high, between  $0.1$  and  $1 \text{ mol l}^{-1}$  or more, that the changes in conductivity caused by the analyte ions are practically undetectable. The only hope of detecting and measuring the conductivity changes lies in using very dilute eluent solutions, which, in turn, require ion exchangers of low capacity. This was the challenge that was faced by the developers of IC.

Even with the dilute eluents used in IC, the background conductivity is at least 10 times, and usually 1000 or more times the conductivity change that is in the analytical signal. The ratio of signal to background depends on the width of the chromatographic peak, the quantity of analyte injected, and the concentration of the eluent, as well as on the equivalent conductivities of the ions taking part.

There are two ways to overcome this difficulty. One is to accept the background conductivity and make it as small as possible by keeping the eluent concentration low. The signal is made as large as

possible by the correct choice of the eluent, and the baseline conductivity is offset electrically. As conductivity rises strongly with temperature, a sensitive and stable conductivity detector is essential, along with good temperature control. The second way to handle the background conductivity is to remove the excess eluent, or convert it to a low-conducting form, before the effluent from the column enters the detector. This operation requires a device called a 'suppressor'. The first method is called 'non-suppressed' or 'single-column' IC. The second is called 'suppressed' IC.

Contemporary conductivity detectors have full output ranges of 0.01–300  $\mu\text{S}$ , which is more than five orders of magnitude, electronic noise of  $\sim 0.2$  ns, cell volume of  $\sim 1$   $\mu\text{L}$ , and temperature stability of oven cell of  $\pm 0.01^\circ\text{C}$ . These characteristics allow one to reach high sensitivity and stability.

## Nonsuppressed Ion Chromatography

The eluent concentrations used in nonsuppressed detection are usually below  $0.01 \text{ mol l}^{-1}$ , and are often  $\sim 1 \text{ mmol l}^{-1}$ . They must, of course, match the capacity of the exchanger, which is commonly  $\sim 10 \text{ mequiv g}^{-1}$ . The typical gel-type cation-exchange resins have capacities of  $\sim 5 \text{ mequiv g}^{-1}$ . Eluents for cations include nitric acid for singly charged alkali metal ions and ethylenediammonium salts for doubly charged alkaline earth metal ions. Because the hydrogen ion has a weak affinity for sulfonic acid-type exchangers, relatively high concentrations must be used, up to  $0.01 \text{ mol l}^{-1}$ . The conductivity decreases when the alkali metal ions emerge.

In anionic IC, the common eluents are benzoate, phthalate, and salicylate. Their equivalent conductances are quite low; therefore, the conductivity of the effluent rises as simple inorganic anions like chloride and nitrate emerge. Because of their aromatic ring structure, these ions have a high affinity for polystyrene-based exchangers, and the eluents can be made dilute without unduly increasing the elution time. Phthalate is better than benzoate in that the fully deprotonated ions are doubly charged; doubly charged ions are more strongly bound than singly charged ions. The ionization constants ( $\text{pK}_a$  values) of phthalic acid ( $\text{H}_2\text{P}$ ) are 2.9 and 5.5. Above pH 5.5 the doubly charged phthalate ions predominate; below pH 5.5 the dominant ions are singly charged  $\text{HP}^{-1}$ , which have a smaller affinity for the resin. Thus, the displacing power of a phthalate eluent can be adjusted over a wide range by adjusting the pH.

Another suitable eluent for anion chromatography is a solution containing boric acid and a polyol, gluconic acid. These substances combine to give acids that are stronger than boric acid. At pH 8.5, the usual pH for borate–gluconate eluents, most of the acids are ionized and the eluting power is adequate. The conductivity of this eluent is low, and rises when other anions are eluted.

Sodium or potassium hydroxide is occasionally used as eluent in nonsuppressed IC. The hydroxide ion has a high conductivity, so the conductivity falls when other anions are eluted. The reason that this eluent is not much used is that the affinity of the hydroxide ion for the exchanger is low. High concentrations of hydroxide must be used, or long elution times must be accepted. Hydroxide eluents are used for the chromatography of anions of very weak acids: borate, carbonate, cyanide, silicate, sulfide. These anions cannot be detected by suppressed chromatography.

## Suppressed Ion Chromatography

In suppressed IC, the excess of eluent ions is removed or converted to a nonconducting form before the column effluent reaches the detector. Generally, the removal is accomplished by an ion-exchange resin of opposite charge to the exchanger used in the separator column. Consider the separation of sodium and potassium ions on a column of cation-exchange resin, with dilute nitric acid as the eluent. These ions come out of the column as their nitrates, accompanied by a considerable excess of nitric acid. If this solution is passed into a column of anion-exchange resin in its hydroxide form, that is, carrying exchangeable hydroxide ions, the nitrates of sodium and potassium are converted to their hydroxides, while the excess nitric acid is converted to water, the nitrate ions being held back in the exchanger. A conductivity detector placed after this column 'sees' peaks caused by the highly conducting sodium and potassium hydroxides, rising from a background conductivity that is nearly zero.

Two anions, say chloride and bromide, could be separated on a column of anion-exchange resin with sodium hydroxide solution as the eluent. They would emerge from the column as their sodium salts, accompanied by a large excess of sodium hydroxide. If this solution is passed through a column of cation-exchange resin that carries hydrogen ions, sodium chloride and sodium bromide form hydrochloric acid and hydrobromic acid, while the excess sodium hydroxide forms water, the sodium ions being retained by the cation-exchange resin.

As already noted, the hydroxide ion has weak displacing power. The retention of bromide, for instance, in a sodium hydroxide eluent would be excessively long, and the peak, when it appears, would be broad and shallow. Another objection to sodium hydroxide is that it readily absorbs carbon dioxide from the atmosphere. Carbonate ions and hydrocarbonate ions are much more strongly held by anion exchangers than are hydroxide ions; carbonate is more strongly held than hydrocarbonate. Thus, a favored eluent for anion chromatography is a mixture of sodium carbonate and sodium hydrogencarbonate, concentrations  $2.2$  and  $2.8 \text{ mmol l}^{-1}$ , respectively. Of course, these concentrations and their ratio can be varied; the higher the proportion of doubly charged carbonate ions, the greater the displacing power. Mixtures of carbonate and hydroxide ions are also used.

When carbonate or hydrocarbonate ions are passed into a column of cation-exchange resin in its hydrogen form, they are converted to carbonic acid, which has a low conductivity. Ions of strong acids, like  $\text{Cl}^-$  and  $\text{Br}^-$ , produce their respective acids, which are highly conducting.

In the early form of IC, columns of high-capacity, gel-type cation- and anion-exchanger resins were indeed used to remove the excess eluent; they were placed immediately after the separator columns, which were packed with low-capacity, surface-functional exchangers. These high-capacity columns were called suppressor columns. They were clumsy, because they needed regeneration from time to time, and they caused additional band spreading. Today, their place has been taken by ion-exchange membranes. The evolution of suppressors is presented in Table 3.

## The Membrane Suppressor

An ion-exchange membrane is simply an ion-exchange polymer in the form of a thin sheet or film. It swells in water, and its internal structure is like that of the gel-type exchanger beads. The

internal concentration of fixed ions should be as high as possible. Cation-exchanging membranes have fixed negative charges and anion-exchanging membranes have fixed positive charges. The counterions can exchange with other ions of like sign in the surrounding solution, and if a suitable force is applied, such as an electric field or a concentration difference, counter-ions can flow across the membrane, always maintaining electrical neutrality. Co-ions, on the other hand, are excluded from the membrane in accordance with the Donnan equilibrium. Exclusion is not total, but nearly so. The passage of co-ions across the membrane is determined not only by their (very small) internal concentration but also by their speed of diffusion.

Suppose that the effluent from a cation-exchange column, containing sodium chloride plus excess hydrochloric acid, is made to flow along one side of an anion-exchanging membrane, while on the other side of the membrane a solution of a quaternary ammonium hydroxide is flowing. (The quaternary ammonium ion is chosen for its slow diffusion rate.) The cations,  $\text{Na}^+$ , cannot enter the membrane; chloride ions enter the membrane and change places with hydroxide ions. Hydroxide ions combine with hydrogen ions in the effluent to form water; sodium hydroxide, in equivalent amount to the sodium chloride originally present, flows on. The effect is just like that of the suppressor column previously described, except that regeneration of the suppressor device is continuous and there is less band broadening.

In IC, a device is used (Figure 4) that has two membranes mounted very close together – dimensions of  $\sim 1 \text{ cm}$  by  $15 \text{ cm}$ , spaced some  $50 \mu\text{m}$  apart, with a mesh of ion-exchange fibers in this space to deflect the flowing stream on to the membrane walls. On the outsides of the membranes are channels through which the regenerating solution, tetramethylammonium hydroxide in our example, flows in the opposite direction to the eluent.

For the chromatography of anions, cation-exchange membranes are used, and the regenerant is

**Table 3** Evolution of suppression devices

	<i>Suppression systems</i>	<i>Year</i>	<i>Note</i>
1	Packed column suppression	1975	(Small e.a.) only isocratic operation
2	Hollow – fiber suppressor	1981	External regeneration solution
3	Micromembrane suppressor	1985	Expanded to gradient operation
4	Autoregeneration	1987	Online, continuous regeneration
5	Micromembrane	1991	Electrolytic membrane-based suppressor, 2 mm
6	SRS-1 autosuppression	1992	Self-regenerating suppression, no external regeneration solution; high capacity
7	SRS-ULTRA	1997–2000	Ultimate in reliability and performance

**Figure 4** Membrane suppressor (not to scale). (Reproduced with permission from Walton and Rocklin (1990) *Ion Exchange in Analytical Chemistry*. Boca Raton, Florida: CRC Press; © CRC Press.)

commonly a solution of sulfuric acid. Sodium chloride is now converted to hydrochloric acid, and sodium hydrogencarbonate or carbonate eluent is converted to carbonic acid. (The concentration is too low to form carbon dioxide gas.) Some of the carbon dioxide diffuses as neutral molecules through the suppressor membranes.

The eluents used in suppressed IC must obviously be compatible with the membrane suppressor. An interesting eluent for cation chromatography is 2,3-diaminopropionic acid (DAP).

The ionization constants are ( $\text{pK}_a$  values) 1.3, 6.7, and 9.4. In strongly acid solution, DAP is a doubly charged cation and a strong eluent for chromatography, suitable for eluting doubly charged cations. At pH 4.0, the singly charged cation predominates. Above pH 6.7, the electrically neutral species predominates. The membrane suppressor converts DAP to the electrically neutral form, which does not conduct electricity.

A great advantage of the membrane suppressor is that it can suppress fairly concentrated effluents, up to  $0.1 \text{ mol l}^{-1}$ , a useful property in analyzing complex samples where one is looking for minor components in the presence of several other materials. There is less chance of overloading the column.

Another significant advantage is that gradient elution becomes possible. It is impossible to carry out gradient elution if the background conductivity is changing steeply during the run.

## Other Detection Methods

Any of the methods of detection used in liquid chromatography can be used in IC, though some are more useful than others. If the eluent does not affect the detector the need for a suppressor disappears. Common means of detection in IC are: ultraviolet (UV) absorption, including indirect absorption; electrochemical, especially amperometric and pulsed amperometric; and postcolumn derivatization. Detectors: atomic absorption spectrometry, chemiluminescence, fluorescence, atomic spectroscopic, refractive index, electrochemical (besides conductivity) including amperometric, coulometric, potentiometric, polarographic, pulsed amperometric, inductively coupled plasma emission spectrometry, ion-selective electrode, inductively coupled plasma mass spectrometry, bulk acoustic wave sensor, and evaporative light-scattering detection.

### Ultraviolet Absorption

Most simple inorganic cations and anions are transparent in the UV, but the larger, more polarizable anions absorb UV radiation, absorbing more strongly at shorter wavelengths. Absorbances at 200–210 nm are sufficiently strong to detect bromide, iodide, nitrate, nitrite, thiocyanate, thiosulfate, and chromate. Carboxylate ions absorb satisfactorily below 215 nm.

In indirect UV detection, an eluent is used that absorbs in the UV region, for example, benzoate or salicylate solution. When an ion emerges from the column that is transparent in the UV, like chloride, the concentration of eluent ions drops (see Figure 3): the absorbance decreases, and a negative peak is produced by the detector. In cation-exchange chromatography, an eluent containing cerium(III) ions has been used. The main difficulty with indirect UV detection is that the drop in absorbance is observed against a large background.

### Electrochemical Methods

**The basic advantages and features of amperometric detection** Amperometric detection is based on measuring of an electrical current arising during oxidation (reduction) of a decomposed substance on the surface of a working electrode, under a certain potential. The amperometric detector has series of

advantages: (1) a low limit of detection ( $10^{-9}$ – $10^{-13}$  g); (2) high selectivity of microimpurity in objects of an environment, in foodstuff, in biological liquids is detected in the analyte with a low limit of detection, thus the basic substances (matrix) are not detected by the detector; (3) small volume of the cell (0.1–5  $\mu$ l); (4) the simplicity of design; and (5) low cost (in comparison with optical detectors the amperometric detector is cheaper).

Halide, sulfide, and cyanide ions have been detected by passing the column effluent along a surface of metallic silver that is maintained at a positive potential. When one of these ions passes, a silver atom releases an electron to form a silver ion, which is precipitated or complexed; simultaneously, at the counter-electrode, a hydrogen ion accepts an electron to form a hydrogen atom, and current flows.

Few simple inorganic ions can be reduced or oxidized electrochemically, but many organic anions can be oxidized at an electrode of gold or platinum. The electrode can be fouled by partly oxidized decomposition products, which is a problem for reproducibility of results. Fouling can be avoided by the 'pulsed amperometric' technique. The electrode is first held for a few hundredths of a second at the working potential, a potential that is sufficiently anodic to oxidize the analyte eluting from the column, and the current is measured and recorded. Then, the potential is raised to a high value to convert any solid oxidation products to carbon dioxide. During this step the metal surface is also oxidized, so that a third step is necessary in which the electrode is held at a negative potential to reduce the oxide back to the free metal. Then the working potential is re-established and the cycle is repeated. The current at the working potential is proportional to the concentration of oxidizable material in the effluent.

Various electrodes are suitable for detection (see Table 4).

Pulsed amperometric detection (PAD) is used with good success in the chromatography of sugars. Sugars are very weak acids with  $pK_a$  values  $\sim 12$ – $14$ , and they can be separated by anion exchange with  $0.01$ – $0.1$  mol  $l^{-1}$  sodium hydroxide as eluent. As can be seen by writing the half-reaction for the oxidation of a sugar, a high pH is necessary for this oxidation to take place. PAD in alkaline solution detects many organic compounds, including amino acids and ascorbic acid.

Sugars are more commonly analyzed on a 'carbohydrate column'. This is packed with a gel-type, high-capacity cation-exchange resin loaded with calcium ions. The eluent is pure water, and detection is usually by refractive index. Sugars and polyhydric alcohols are retained, primarily, by coordination of hydroxyl groups with the calcium ion. The stability of the coordination complex, and hence the retention time, depends on the orientation of these hydroxyl groups, leading to the separation of closely related sugars.

### Postcolumn Derivatization

In this technique, a chemical reagent is pumped into the effluent stream as it comes out of the column. The mixed stream flows through a delay coil to allow time for the reaction to become complete, after which it passes into the detector. A good example of a postcolumn reaction is the ion-exchange chromatography of amino acids. These compounds do not absorb light themselves, but they combine with certain reagents to form strongly colored or fluorescent products. Ninhydrin forms red or purple products; o-phthalaldehyde plus a thiol yields products that are strongly fluorescent and allow very sensitive

**Table 4** The list of types of working electrodes and substances determined on them

<i>Material of a working electrode</i>	<i>Determined substances</i>
Glassy carbon	General purpose, but is most suitable for the analysis of: nitrite, sulfide, bromide, iodide, cyanide, sulfide, disulfides, etc.
Gold	Aliphatic alcohols, monosaccharides, disaccharides, oligopolysaccharides, aliphatic amines, aminoalcohols, amino sugars, amino acids
Platinum	Hypochlorite, arsenite, hydrazine
Silver	Cyanide, sulfide, thiosulfate, thiocyanide, bromide, iodide, hydrosulfide
Copper	Carbohydrates, amino acid, peptides, polypeptides, protein
Nickel	Carbohydrates, alcohols, amino acid
Palladium	Aromatic hydrocarbons

Other electrodes: electrodes modified by enzymes; electrodes modified by current-carrying polymers; electrodes modified by phthalocyanines, ferrocene, etc.

Admixture and alloys: Ni–Ti, Ni–glassy carbon, Ni–Cr, Ni–Cu, Ni–Cr–Fe, Pt–glassy carbon, Au–Cr, Co, etc.

detection. In inorganic analysis, postcolumn derivatization is used to detect and measure ions of transition metals and lanthanides. Reagents used for this purpose are 4-(2-pyridylazo)resorcinol, and the 'Arsenazo' dyes. They give products that absorb strongly in the visible region.

## Introduction

When first developed, ion chromatography (IC) was based on the use of a low-capacity anion exchange separator column used with a basic eluent and a suppressor column, with conductimetric detection. This allowed the sensitive detection of a limited number of inorganic anions in aqueous samples in reasonably short analysis times. Later work saw the introduction of nonsuppressed IC, which utilized low-conductivity eluents, mainly organic aromatic weak acids, that could be used without a suppressor module, thus simplifying the chromatographic system. Nonsuppressed IC, being less sensitive than suppressed IC, was generally more applied to

samples containing higher solute concentrations. Improvements in stationary-phase technology led to more efficient simultaneous separations of inorganic and organic anions, and combined with the development of improved suppressor systems, such as self-regenerating membrane suppressors, this saw IC establish itself as the method of choice for anion analysis of aqueous samples. In the application of IC to the determination of organic and inorganic cations, there has also been much progress. Again, both suppressed and nonsuppressed IC systems have been used, predominantly for the determination of alkali and alkaline earth metal ions and organic amines, again mostly in aqueous-based sample matrices. The following is a simple review of some of the more interesting applications of IC, focusing on those applications based on the use of ion exchange stationary phases, although alternative approaches to the separation of ionic species, such as ion interaction liquid chromatography, will also be included.

## Environmental Applications

### Natural Waters

**Inorganic anions** One of the commonest applications of IC is the analysis of natural nonsaline water samples, such as subsurface waters, spring waters, streams, river waters, and lakes. Particular interest lies in the use of IC as a laboratory-based technique for the routine monitoring of the above sample types for nutrient anion concentrations, such as nitrates, nitrites, sulfates, and phosphates. In most cases suppressed IC is used, due to its ability to quantify the above species, which are often present at sub-mmol l<sup>-1</sup> concentrations. The US EPA Method 300 (Determination of fluoride, chloride, nitrite, nitrate, phosphate, and sulfate in water samples by IC) describes suitable conditions for this particular application, based on the use of a Dionex IonPac AS4A anion exchange column, with a carbonate/bicarbonate eluent (or a similar stationary-phase/eluent combination that produces similar or better selectivity and efficiency) and suppressed conductivity detection. Utilizing these conditions, resolution of the above anions from each other and matrix anions, typically chloride, is possible. Approximate linear ranges quoted for the above anions, using a similar analytical setup to that described above, are between 0.01 and 5 mmol l<sup>-1</sup>, with detection limits in the order of 0.1–1 µmol l<sup>-1</sup>. Similar detection limits for nitrate and nitrite can be achieved using IC combined with direct UV absorbance detection at 225 nm. In this case large matrix peaks resulting from excess sulfate and chloride are essentially eliminated due to their UV transparency at this wavelength. With IC applications utilizing direct UV detection, the eluting anion within the mobile phase must also be UV transparent if sensitive detection is to be obtained.

Nonsuppressed IC methods for natural water samples are generally 1–2 orders of magnitude less sensitive for common inorganic anions than suppressed conductivity methods, but still find useful application for the determination of higher-concentration matrix anions, such as chloride and sulfate. Typical eluents used include *p*-hydroxybenzoic acid or phthalic acid, often used with small amounts of organic solvent to improve peak shapes. Such eluents can also be employed for indirect UV detection, although again sensitivity is somewhat less than for direct UV detection.

The determination of the above nutrient anions in natural saline samples, such as coastal seawaters, is also of interest to environmental scientists, and several IC methods have been developed that can tolerate the high salt content of such samples. Column switching techniques have been used for this type of application.

Saline samples are injected onto short high-capacity anion exchange guard columns, which are separated from the main analytical anion exchange column by a switching valve. Correct timing of the switching valve allows the early eluting excess chloride to be directed to waste before the more retained anions of interest, such as bromide, phosphate, sulfate, nitrite, nitrate, and residual chloride, are eluted. Redirecting the later eluting anions onto the analytical column allows separation and detection to take place and eliminates large-matrix chloride peaks.

An alternative approach is to include the matrix anion in the eluent itself, so-called 'matrix elimination IC'. Here a sodium chloride eluent is used with a strong anion exchange column, thus eliminating any 'self-elution' problems when analyzing saline samples. The method is most suitable for strongly retained anions such as iodide, and has indeed been used for the determination of this particular anion in seawater samples, with trace level detection made possible through postcolumn reaction and visible absorbance detection.

**Inorganic cations** For the determination of common inorganic cations in nonsaline natural waters, IC competes with atomic spectroscopy as the method of choice. Despite this, IC is used by many monitoring agencies for the determination of alkali and alkaline earth metal cations and, to a lesser extent, selected transition metal cations. Two approaches are commonly taken. Firstly, for the determination of alkali metal ions, a strong cation exchanger (sulfonated) is generally used with a strong acid eluent and combined with suppressed conductivity detection. For the simultaneous determination of alkali and alkaline earth metal ions, a weaker cation exchanger (carboxylated or carboxylated and phosphonated, e.g., a Dionex IonPac CS12A column) is more suitable, and used with a weaker eluent and either suppressed conductivity detection or indirect conductivity detection. Such a system allows the simultaneous determination of lithium, sodium, ammonia, potassium, magnesium, and calcium in water samples (EPA Method 300.7).

### Treated Waters

Treated waters for domestic use are routinely analyzed using IC for both naturally present common inorganic anions and trace anionic contaminants, several classes of which actually originate as by-products of the treatment processes themselves. Oxyhalides, which originate from various drinking water disinfection processes, such as chlorination and ozonation, can be found present in finished drinking

waters and require monitoring at sub-micromolar concentrations. For example, chlorate and chlorite can result from treatment with chlorine dioxide, and bromate and iodate can be formed from the treatment of bromide- and iodide-containing drinking waters with ozonation. The 1998 European Drinking Water Directive set a mandatory standard limit of  $10 \mu\text{g l}^{-1}$  for bromate in drinking water to be in place by 2008, necessitating sensitive analytical methods for this particular analyte to be developed. When using IC for the determination of bromate in drinking water, a high-capacity anion exchange column is generally used to allow the injection of larger sample volumes, thus improving detection limits. Detection of ultra-trace levels of bromate is achieved via postcolumn reaction, followed by visible detection (450 nm), using *o*-dianisidine dihydrochloride (as in EPA Method 317.0). Alternative detection can be achieved via postcolumn reaction with potassium iodide–ammonium heptamolybdate (triiodide method), although both methods result in a similar sensitivity for bromate with detection limits of  $\sim 0.5 \mu\text{g l}^{-1}$ . **Figure 1** shows an ion chromatogram of a mixture of common inorganic anions and trace oxyhalides, here using only suppressed conductivity detection (obtained using EPA Method 300.1, Part B).

**Figure 1** Chromatogram of 10 inorganic anions and oxyhalides in a water sample using suppressed ion chromatography. Peak identification: 1 = fluoride, 2 = chlorite, 3 = bromate, 4 = chloride, 5 = nitrite, 6 = bromide, 7 = chlorate, 8 = nitrate, 9 = phosphate, 10 = sulfate. (Reprinted with permission from Saari-Nordhaus R and Anderson JM Jr. (2002) Recent advances in ion chromatography suppressor improve anion separation and detection. *Journal of Chromatography A* 956: 15–22; © Elsevier.)

Two compounds that are currently generating much concern are azide and perchlorate, salts of which are currently used in the explosives and pyrotechnics industry, with perchlorate also used as a primary oxidant in solid rocket fuel. IC can be used for the monitoring of both analytes in natural and treated waters. For perchlorate, EPA Method 314.0 (Determination of perchlorate in drinking water by ion chromatography) has been developed, which suggests the use of a Dionex IonPac AS16 anion exchange column (or equivalent) with a 35 mM NaOH eluent and suppressed conductivity detection.

Finally, there has also been much interest in recent years in the contamination of groundwater, well water, and drinking water supplies with hexavalent chromium. An EPA method has been developed utilizing IC for hexavalent chromium determinations (EPA Method 218.6). This method specifies the use of a high-capacity Dionex IonPac AS7 anion exchange column and UV/Vis detection following post-column reaction with diphenylcarbazine. **Figure 2** shows an ion chromatogram of a spiked and unspiked drinking water sample obtained using a modified version of EPA Method 218.6.

**Table 1** lists some of the IC methods prescribed by the US EPA for the analysis of drinking water including several oxyhalide disinfection by-products (DBPs).

Note how inductively coupled plasma mass spectrometry (ICP-MS) is also used for bromate detection in Method 321.8.

### Soil Analysis

**Inorganic anions** IC is used extensively for the determination of common inorganic anions in soil extracts. The key to valuable data when carrying out such analyses is the use of correct and reproducible extraction methods. For the determination of inorganic anions, often the soil is simply extracted using water. Such an application of IC is used to provide information on the fate of nutrient anions resulting from agricultural practices and to determine soil nutrient retention and leaching rates.

**Organic anions** Both anion exchange chromatography and ion exclusion chromatography have been used extensively for the determination of low-molecular-weight organic acids in soil extracts. Malic acid, malonic acid, maleic acid, succinic acid, fumaric acid, ascorbic acid, citric acid, isocitric acid, succinic acid, tartaric acid, oxalic acid, and glycolic acid can all be determined using these techniques.

**Inorganic cations** For the extraction of cations from soils, a number of approaches are used, dependent on whether the analyst wishes to determine labile or nonlabile cation concentrations. Extractions can be carried out using simply water or electrolyte solutions, or strong acid solutions for nonlabile cations. In this way, IC can also be used to determine the ion exchange capacity of the soils in question.

Recently, IC has also found increased application in the field of metal speciation. Short anion exchange columns have been used for the rapid separation of anionic species of arsenic, selenium, and chromium,

extracted from contaminated soils, and followed by elemental specific detection.

### Atmospheric Samples

The determination of ambient concentrations of gaseous nitrogen- and sulfur-containing species (predominantly nitrate and sulfate) in the atmosphere has also been carried out using IC after collection using passive samplers. Wet denuder systems have also been developed for the collection of soluble ionogenic trace gases and soluble ionic species adsorbed onto atmospheric particles, used on-line with IC for continuous monitoring purposes.

The use of large-volume filter-based samplers for the collection of atmospheric particulates has also been combined with IC for the determination of absorbed metal species. Collected samples are extracted from the filters and desorbed from the particulate matter using acidic solutions prior to analysis by IC combined with elemental selective detection such as ICP-MS. Hexavalent chromium, platinum, and palladium have been determined in this way, as have many other transition and heavy metal ions.

**Rainwater** Automated rainwater collectors have been used in combination with IC for the determination of low-level concentrations of dissolved inorganic anions or cations. Due to the 'clean' nature of the sample, online preconcentration of the analytes can be readily achieved using short ion exchange preconcentrator cartridges onto which large sample volumes can be loaded, prior to elution onto the appropriate separator ion exchange column. This approach is used for the ultratrace analysis of rainwater samples.

**Table 2** Examples of foodstuffs to which IC has been applied for anion determinations following appropriate extraction methods

<i>Anions</i>	<i>Sample matrix</i>
Nitrate, nitrite, sulfate, phosphate, chloride	Milk products, fruits and fruit juices, beverages and alcoholic products, meat products, bakery products, vegetables, cereals
Fluoride	As above plus citrus fruits and leaves and spinach
Iodide	Seafood, food colorings, and iodized table salt
Sulfite	Beer, lemon juice, potatoes, seafood, fruits (grapes)
Bromide	Milk, food colorings, rice products, bakery products
Chlorite and chlorate	Vegetables
Bromate	Bakery products
Iodate	Iodized table salt
Chromate	Orange juice, potato products
Selenite and selenate	Vegetables, cereals, orange juice
Arsenite and arsenate	Food supplements, cereals, vegetables
Cyanide	Fruits and fruit juices

An alternative approach has been developed based on a weakly acidic cation exchange column, used with a dilute tartaric acid/crown ether eluent, which resulted in the ability to separate both inorganic anions (chloride, nitrate, and sulfate) and inorganic cations (sodium, potassium, ammonium, calcium, and magnesium) simultaneously in real rainwater samples. The anions were retained through an ion exclusion mechanism and the cations were retained through a simple cation exchange mechanism. Sensitive detection was achieved using direct conductivity.

## Industrial Applications

### Food and Beverages

As with most chromatographic methods applied to solid samples, sample digestion and analyte extraction methods are all important. IC is finding application in the analysis of foodstuffs following sample preparation using such techniques as microwave digestion, supercritical fluid extraction, accelerated solvent extraction, and pyrohydrolysis.

**Inorganic anions** The predominant anionic species determined in foodstuffs are once again the nitrogen-, sulfur-, and phosphorus-containing species, as well as the halide ions. Table 2 lists some inorganic anions and some of the foodstuffs that have been analyzed for these anions using IC.

Some of the more important applications in food analysis include nitrates and nitrites in baby food products, excess of which can lead to induce methemoglobinemia (blue baby syndrome), and the monitoring of sulfite, which is added to many foodstuffs as a preservative and to bleach food starches, and is only recently being linked to serious health effects. Also, residual bromate can be monitored in bakery products from the continuing use of bromate salts as dough conditioners.

**Organic acids** In beverages such as wines, beers, and fruit juices, IC has also been widely applied in the determination of various organic acids, although in many cases ion exclusion chromatography is often used in preference to anion exchange.

**Sugars** In the brewing industry, IC is used for the determination and monitoring of fermentable sugars, such as glucose, fructose, isomaltose, sucrose, maltose, maltotriose, and numerous others. For sensitive detection, pulsed amperometric detection is often preferred.

**Inorganic and organic cations** In the analysis of foodstuff extracts and digests, IC has been predominantly applied to the determination of alkali and alkaline earth metal ions and, to a lesser extent, selected organic amines. Alkali and alkaline earth metal ions are naturally present in most foodstuffs, although accurate monitoring is still necessary to evaluate nutritional values, e.g., the sodium or calcium content of foodstuffs. As mentioned previously, ammonium content can also be determined using IC simultaneously with alkali metal ions, and is often used as an indicator of food quality.

Transition and heavy metal ions have also been determined in foodstuffs using IC, particularly seafood, where heavy metal contamination with metals such as cadmium and lead is often a problem. After separation using cation exchange or ion interaction chromatography, sensitive detection is generally achieved using postcolumn reaction detection with a suitable color-forming ligand, such as 4-(2-pyridylazo) resorcinol (PAR). Other metals such as zinc, copper, iron, cobalt, nickel, chromium, and manganese can also be detected in this way.

In an interesting recent application, the determination of acrylamide in foodstuffs has been shown using accelerated solvent extraction followed by IC

with either UV or MS detection. Extracted samples can be analyzed directly using IC, with limits of determination of 50 ng per g acrylamide in foodstuffs possible using MS detection with single ion monitoring (SIM) at  $m/z$  72.

### Pharmaceuticals

In the preparation of pharmaceutical products, the purity of reagents is of utmost importance. IC is often used for trace anion and cation determinations in starting materials, the simplest of which is reagent grade water. However, actual pharmaceutical preparations are often complex mixtures and IC provides alternative column selectivity to standard reversed-phase HPLC, and is often more suited for the separation of very polar organics commonly used in pharmaceutical products. Table 3 lists some of the organic species that have been determined using IC. Often for such analytes UV absorbance is the preferred mode of detection, provided the analyte contains a suitable chromophore.

### Nuclear and Fossil Fuel Power Generation Industry

As with the pharmaceutical products above, there is also great concern over contamination problems in the power generation industry. IC is extensively used to determine ultratrace concentrations of ionic species in process waters, coolant waters, wastewater, and other waste materials. The popularity of the technique is due to IC being one of a few analytical technologies that is able to measure ng per g concentrations of potentially corrosive ions such as

sodium, chloride, and sulfate on a near-real-time basis, and can also differentiate among different oxidation states of ions such as nitrate, nitrite, sulfate, and thiosulfate. These oxidation states respond to the general oxidizing tendency of coolant waters, which is an important variable in controlling localized corrosion. Some impressive recent applications of IC within this industry include: the determination of mono-, di-, and tributyl phosphates, the latter of which is an important compound used in the area of nuclear fuel reprocessing; the determination of long-lived artificial radionuclides resulting from fission reactions using IC coupled to ICP-MS detection; the use of IC to determine amines in amine-dosed feedwater used for erosion control in boiler tubes; and the application of IC to the determination of transition metal cations in the primary coolants of light water reactors. Figure 3 shows an ion chromatograph of a condensate discharge water sample from a fossil fuel power station containing trace amounts of inorganic anions and organic acids.

### Semiconductor Industry

The semiconductor industry utilizes IC to monitor and identify the possible contamination of products during manufacture. Much of the application of IC is to trace inorganic anion analysis and, to a lesser extent, trace alkali and alkaline earth cation determinations. The sample matrices that are monitored using IC in the semiconductor industry include the large variety of chemicals used for cleaning,

**Table 3** Examples of pharmaceutical preparations to which IC has been applied

<i>Analytes</i>	<i>Sample matrix</i>	<i>Column</i>	<i>Detection method</i>
Citrate	Liquid and tablet formulations	Anion exchange	Indirect UV absorbance
Saccharin aspartane, acesulfame-k, benzoate, sorbate, caffeine, theobromine, theophylline	Tablet preparations	Anion exchange	Tunable UV absorbance
Trifluoroacetate	Cell-based products	Anion exchange	Suppressed conductivity
Alenalol, metaprolol, alprenolol, oxprenolol, acebutolol, propanolol	$\beta$ -Blocker tablet preparations	Anion exchange	Tunable UV absorbance
Paracetamol, salicylate	Tablet preparations	Anion exchange	UV absorbance
Alkyl sulfonic acids	Sulfonated sugar preparations	Anion exchange	Suppressed conductivity
Alendronate	Dosage formulations	Anion exchange	Electrospray mass spectrometry
Catecholamines (norepinephrine, epinephrine, dopamine)	Injection formulations	Cation exchange	Nonsuppressed conductivity
Tetracyclines	Antibiotic preparations	Cation exchange	UV absorbance
Amylamine, <i>t</i> -butylamine	Hypocholesterolemic agent preparations	Cation exchange	Nonsuppressed conductivity

**Figure 3** Ion chromatogram of a condensate discharge water sample. Peak identification: 1 = fluoride, 2 = acetate, 3 = formate, 4 = chloride, 5 = nitrite, 6 = carbonate, 7 = sulfate, 8 = unknown, 9 = nitrate, 10 = unknown, 11 = phosphate. washing, polishing, and treating surfaces, such as reagent water, solvents, strong acids and bases, and oxidizing agents. Process gases and clean room gases, and filtered air are also monitored.

## Biological Applications

### Analysis of Blood, Plasma, and Serum

The ability to determine quantitatively certain ionic analytes in blood, plasma, and serum samples can be of substantial benefit to those attempting the diagnosis of certain diseases, particularly where concentrations of these analytes are known to be directly related to specific physiological disorders.

**Anions** IC has established itself as the method of choice for the determination of common anions such as chloride, sulfate, and phosphate in blood and serum samples. For example, a common clinical application of IC is the study of sulfa drug metabolism through the monitoring of blood sulfate levels. Samples are generally pretreated using ultrafiltration or acidification and centrifugation, or both. Both IC and ion exclusion chromatography have been applied to the determination of bicarbonate in blood plasma. Ion exclusion has also been extensively applied to the determination of certain organic acids in blood plasma, such as pyruvate and lactate, the latter of which is used to

help in the diagnosis of lactic acidosis in diabetic patients.

**Cations** There have been many applications of IC to the determination of sodium, potassium, and ammonium in blood serum. In most cases, serum samples were simply ultrafiltered and injected directly. In other cases only dilution was necessary. Total and free concentrations of calcium and magnesium in blood serum can also be determined using IC. Total concentrations can be determined using sample acidification followed by centrifugation. Free concentrations of the cations can be determined after passage of the untreated sample through a cation exchange solid-phase extraction (SPE) cartridge to trap the cations and isolate them from those ions bound to serum proteins.

### Analysis of Urine

As with blood, urine analysis is used in clinical studies, and the relative concentrations of various ionic species are of great importance in both disease diagnostic and drug metabolism studies. For example, IC is used to determine urine oxalate concentrations. Urinary oxalate levels are an important parameter in urolithiasis research (kidney stones). Other anions that can be determined in urine using IC include phosphate, sulfate, bromide, citrate, nitrate, nitrite, and thiosulfate. As with blood and serum samples, both ultrafiltration and centrifugation are often used as sample cleanup steps.

Interesting applications include the use of IC coupled with ICP-MS detection for the determination of anionic arsenic species in urine resulting from occupational and dietary exposure. Species include urinary arsenate, arsenite, dimethylarsinic acid, and methylarsonic acid, and are separated using a hydrophilic anion exchange resin with a weak acid eluent. Studies have also been carried out using IC and ion interaction liquid chromatography to determine human urinary thiocyanate concentrations and relate concentrations found to levels of smoking. Thiocyanate is the main metabolic product of cyanide inhaled with cigarette smoke. **Figure 4** shows overlaid ion chromatograms of a smoker's urine sample and the same sample spiked with thiocyanate. The chromatograms shown were obtained using ion interaction chromatography, utilizing a short reversed-phase column and a tetrabutylammonium chloride and methanol eluent. Detection was carried out using direct UV absorbance at 230 nm.

### Analysis of Saliva and Sweat

Finally, IC methods have been applied to the determination of both inorganic anions and alkali and

**Figure 4** Analysis of urine for thiocyanate using ion interaction liquid chromatography. Lower trace: sample (heavy smoker) diluted 1:20. Upper trace (heavy smoker) diluted 1:20 and spiked with thiocyanate.

alkaline earth cations in saliva. The sample matrix is relatively simple compared to other biological fluids and can be analyzed directly or simply diluted prior to injection.

IC methods have also been developed for the determination of sweat samples for ionic analytes. Methods looking at sulfate levels and also concentrations of sodium and potassium in sweat samples have been developed, with relative levels of the latter metal ions being useful indicators of several important diseases, one of which is cystic fibrosis.

## Introduction

It is now over 60 years since the development of column ion-exchange chromatography using polymeric resins. Interestingly, little has changed since then in terms of the basic separation processes for inorganic anions and cations. The renaissance in the 1970s, where ion-exchange was the principal process in a group of techniques now known as ion chromatography (IC), was mainly associated with the improvement in efficiency of stationary phases and detection systems rather than new types of ion-exchange groups or elution systems. In essence, the IC separation of metal ions principally involves the use of eluents containing complexing organic acids,

such as tartaric, citric, oxalic, combined with high efficiency stationary phases. The complexing strength of acid and concentration chosen depended on whether the ion-exchange substrate was cationic, anionic, or mixed. Although poly(styrene-divinylbenzene) (PS-DVB) based resins are still the most common substrate, silica-based materials are increasingly being used.

There are a number of problems associated with present IC methods involving high efficiency ion-exchange separations of metal ions, the two principal ones being sensitivity to ionic strength and limited selectivity. The influence of ionic strength is particularly serious as a relatively large salt concentration in the sample can drastically affect the chromatography, in many cases making it impossible to resolve the analytes. Limited selectivity is also a restriction, as once the substrate is chosen for conventional ion-exchange separations there are only a small number of cases where changes in eluent composition can significantly alter separation order.

**Figure 4** Analysis of urine for thiocyanate using ion interaction liquid chromatography. Lower trace: sample (heavy smoker) diluted 1:20. Upper trace (heavy smoker) diluted 1:20 and spiked with thiocyanate.

alkaline earth cations in saliva. The sample matrix is relatively simple compared to other biological fluids and can be analyzed directly or simply diluted prior to injection.

IC methods have also been developed for the determination of sweat samples for ionic analytes. Methods looking at sulfate levels and also concentrations of sodium and potassium in sweat samples have been developed, with relative levels of the latter metal ions being useful indicators of several important diseases, one of which is cystic fibrosis.

## Introduction

It is now over 60 years since the development of column ion-exchange chromatography using polymeric resins. Interestingly, little has changed since then in terms of the basic separation processes for inorganic anions and cations. The renaissance in the 1970s, where ion-exchange was the principal process in a group of techniques now known as ion chromatography (IC), was mainly associated with the improvement in efficiency of stationary phases and detection systems rather than new types of ion-exchange groups or elution systems. In essence, the IC separation of metal ions principally involves the use of eluents containing complexing organic acids,

such as tartaric, citric, oxalic, combined with high efficiency stationary phases. The complexing strength of acid and concentration chosen depended on whether the ion-exchange substrate was cationic, anionic, or mixed. Although poly(styrene-divinylbenzene) (PS-DVB) based resins are still the most common substrate, silica-based materials are increasingly being used.

There are a number of problems associated with present IC methods involving high efficiency ion-exchange separations of metal ions, the two principal ones being sensitivity to ionic strength and limited selectivity. The influence of ionic strength is particularly serious as a relatively large salt concentration in the sample can drastically affect the chromatography, in many cases making it impossible to resolve the analytes. Limited selectivity is also a restriction, as once the substrate is chosen for conventional ion-exchange separations there are only a small number of cases where changes in eluent composition can significantly alter separation order.

There is an alternative to ion-exchange, known generally as chelation ion-exchange, giving greater control over selectivity and relatively unaffected by changes in ionic strength. Although related, chelation ion-exchange differs fundamentally from ion-exchange in that it involves the formation of coordinate bonds between metal ions and a complexing ligand immobilized on the surface of the substrate. Thus, the sorption process in chelation ion-exchange depends mainly upon the values of the stability constants of the metal complexes formed on the stationary phase. Inevitably, because ion-exchange and chelation ion-exchange arise from the same functional group, they can occur together. Nevertheless, conditions can be chosen where chelation ion-exchange is the dominant mechanism controlling separation, as explained in the next section.

It can be seen that the greater versatility of chelation ion-exchange arises from the wide range of complexing ligands available, where selectivity can be altered to suit the trace metal composition of a particular interest and sample type. Chelation ion-exchange is not a recently exploited technique, being used for nearly as long as ion-exchange itself. However, until recently, chelation ion-exchange columns have principally been used for matrix isolation and preconcentration of suites of metals rather than chromatographic separation. The isolation of trace metals from seawater using Chelex 100 (iminodiacetic acid functionalized PS-DVB) is a classic example. Later, chelating ion-exchangers such as 8-hydroxyquinolinol attached to silica (Table 1) have been extensively used in flow injection analysis for determination of metals.

In the last 10 years or so, chelation ion-exchange columns have become available for use as precolumns in IC systems where matrix isolation and preconcentration occur online before the suite of metals is swept onto an ion-exchange column for separation (see later). This approach became known as chelation ion chromatography (CIC). Another use of chelation ion-exchange columns, the main focus of this article, is for the high-efficiency separation of metal ions on small particle size substrates. It is a relatively new approach and shows great potential for the IC determination of metals in a wide variety of complex samples, including those with very high ionic strengths. Although the term CIC can be used to describe both uses of chelation ion-exchange substrates, it should be noted that some workers have preferred to use the term high-performance chelation ion chromatography (HPCIC) to differentiate the high-efficiency separation technique from CIC methods where chelation ion-exchange is only

used for preconcentration or matrix isolation purposes.

The principal purpose of this article is to describe the latest work involving high-efficiency chelation ion-exchange columns for determining trace metals in a wide variety of complex matrices. The basic principles relating to the sorption of metal ions will be described first, followed by illustrations of the different separation modes available, and, finally, key examples will be given of the wide range of samples analyzed by the technique.

## Chelation Ion-Exchange Equilibria

The efficient separation of metal cations can be achieved with three main methods:

1. using conventional cation-exchange based on electrostatic interactions;
2. by preconcentration of metal cations on a short column packed with chelating substrate with further separation by cation-exchange ion chromatography;
3. using the ability of chelating ion-exchangers to achieve analytical separations of metal ions with a single column.

The last two methods can both be described as CIC as discussed earlier. However, it is only with approach (3), the principal concern of this article, is it important to fully understand the factors affecting efficiency and selectivity to obtain good chromatography. Therefore, the basic principles described below will focus on these aspects.

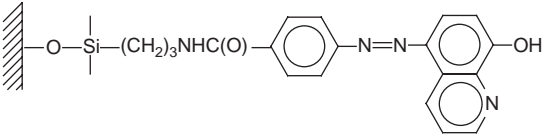

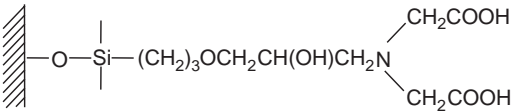

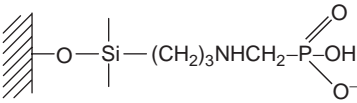

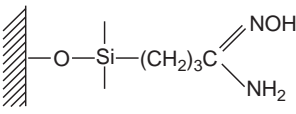

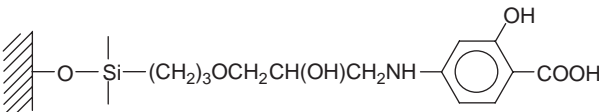

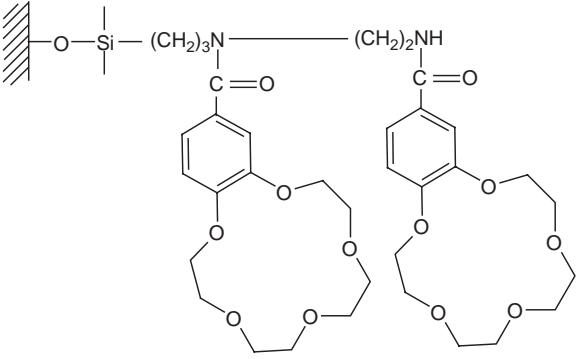

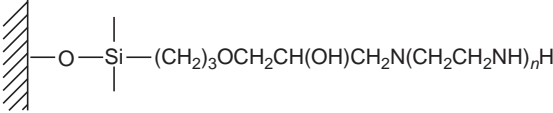

### Distribution Ratio

Pure sorption mechanisms are very rare in chromatography and chelation ion-exchange is no exception. As the chelating groups are usually charged, the chromatographic retention of alkaline-earth, transition, and heavy metal ions on such a column, in a noncomplexing eluent, occurs through the combination of electrostatic and coordination interactions between cations and chelating functional groups on the substrate. The distribution ratio  $D_M$  of metal cation  $M^{y+}$  between chelating ion-exchanger and the contacting mobile phase can be expressed by the following equation:

$$D_M = ([M_R^{y+}]^I + [M_R^{y+}]^C) / [M_{aq}^{y+}] \quad [1]$$

where  $[M_R^{y+}]^I$  and  $[M_R^{y+}]^C$  are equilibrium concentrations of cation retained by the stationary phase due to electrostatic interactions (conventional ion-exchange) and chelation ion-exchange, respectively.

$[M_{aq}^{y+}]$  is the concentration of cation in the mobile phase. The retention factor  $k$  can be expressed as

$$k = (t - t_0)/t_0 = D_M \varphi \quad [2]$$

where  $t$  is retention time,  $t_0$  the void time, and  $\varphi$  is a characteristic constant for a given chromatographic column expressed as the ratio of the volumes of mobile  $V_{aq}$  and stationary  $V_R$  phases:

$$\varphi = V_{aq}/V_R \quad [3]$$

As suitable chromatographic separation can be achieved at values of  $k < 10$ –15 and the formation of complexes at the surface with more than one ligand is for simplification assumed not to take place due to thermodynamic and steric restrictions; then,

Thus,  $[M_R^{(y-x)+}]^C$  can be expressed as follows:

$$[M_R^{(y-x)+}]^C = \beta_1 [M_{aq}^{y+}] [L^{x-}] \quad [5]$$

where  $[L^{x-}]$  is the concentration of functional groups and  $\beta_1$  is the stability constant of complex  $ML^{(y-x)+}$  formed at the surface in accordance with (4).

### Selectivity Ratio

The ion-exchange process of cation  $M^{y+}$  and alkali metal cation  $B^+$  as competing cation at constant pH of the eluent on the chelating ion-exchanger can be expressed as follows:

where the subscript 'aq' denotes the mobile phase and 'R' denotes the stationary phase. The following selectivity ratio is given by

$$K_M^B = \frac{[M_R^{y+}][B_{aq}^+]^y}{[M_{aq}^{y+}][B_R^+]^y} \quad [7]$$

Taking into account the two possible types of interactions in accordance with [1], the retention factor  $k$  of metal cation  $M^{y+}$  can be expressed as

$$k = \left( K_M^B \frac{[B_R^+]^y}{[B_{aq}^+]^y} + \beta_1 [L^{x-}] \right) \varphi \quad [8]$$

The first member of the sum in brackets expresses the impact of conventional ion-exchange interactions on retention, and the second member expresses the impact of chelation on retention. Several conclusions can be formulated from eqn [8].

Assuming little change in  $\beta_1$  with high ionic strength ( $>0.1$ ), the retention of a metal ion due to

chelation should not depend upon the concentration of alkali metal cations  $[B_{aq}^+]$ , but solely on the concentration of functional groups in the chelating ion-exchanger. In practice, it means electrostatic interactions need to be suppressed for chelation to be the dominant sorption mechanism.

The retention of  $M$  due to conventional ion-exchange can be suppressed by increase of  $[B_{aq}^+]$ .

Thus, in the case of domination by chelation ( $\beta_1 [L] \gg K_M^B ([B_R^+]^y / [B_{aq}^+]^y)$  at high concentration level of  $B_{aq}^+$  in the eluent) the separation selectivity  $\alpha$  is defined by ratio of corresponding stability constants of metal chelates formed at the surface:

$$\alpha = k_2/k_1 = \beta_1^{M2}/\beta_1^{M1} \quad [9]$$

Strictly, it should be the ratio of conditional stability constants, but for a given ligand with no hydrolysis of the metal ions, the ratio is the same as the thermodynamic stability constants.

### Temperature Effects

As well as varying the ionic strength of the eluent, the separation selectivity  $K_M^B$  in CIC can be changed by variation of column temperature. Sorption heat relates the retention factor  $k$  with the column temperature by the van't Hoff equation:

$$\ln k = -\Delta H/RT + \Delta S/R + \ln \varphi \quad [10]$$

where  $\Delta H$  and  $\Delta S$  are sorption enthalpy and entropy, respectively, and  $\varphi$  is the phase volume ratio. The temperature effects are exothermic (negative values of  $\Delta H$ ) in the case of conventional ion-exchange. However, the heat values do not exceed 8–13 kJ mol<sup>-1</sup> and therefore have little influence on retention. In contrast, for stationary phases where metal ion complexation is present, the sorption process will normally exhibit much higher values of  $\Delta H$  in both exothermic and endothermic conditions. Thus, temperature effects will be significant and some regulation of selectivity is possible.

### Factors Affecting the Efficiency of Chelation Ion-Exchange

It is very important to understand the factors controlling the kinetics of the sorption process as they will have a major bearing on separation efficiency. There are three factors affecting the kinetics of chelating ion-exchange:

1. transport of metal ion from the mobile phase to the surface of chelating ion-exchanger;

2. diffusion of the ions inside of the stationary phase; and
3. kinetics of chelation of metal ion with functional groups.

The first two factors are similar to those occurring in simple conventional ion-exchange so they will not be discussed further.

The resulting kinetics of chelation depends upon the chemical nature of the functional groups and the structure of the chelating ion-exchanger, with the former being the most crucial for good separations.

### Chemical Nature of Functional Groups

**Charge on the functional groups** It was empirically established that better kinetics of CIC arise when negatively charged functional groups are present. Obviously, negatively charged groups at the surface, attracting oppositely charged cations from the mobile phase, will provide better transport of metal ions from the mobile phase than neutral or positively charged chelating surfaces.

**Dentation of the ligand** It would be expected that the higher the denticity of the ligand, the slower the kinetics as more groups need to be dissociated and more coordinate bonds formed for each metal exchange reaction. In practice, polydentate ligands are usually necessary to achieve adequate retention and selectivity. Fortunately, for most ligands with a denticity not greater than 3, the slower kinetic effect in most cases appears to be relatively minor, as long as the eluent conditions are chosen to ensure small conditional constants.

**Magnitude of the conditional constants** Of all the ligand properties affecting chelation ion-exchange kinetics, the value of the metal/ligand conditional constant has the largest influence. In simple terms, the magnitude of a stability or conditional constant is governed by the ratio of the velocity of the forward reaction (association) to the velocity of the back reaction (dissociation). Except for a small number of metal ion/ligating atom combinations (see later), the velocity of the forward reaction is very fast. Thus, the kinetics of chelation ion-exchange will be controlled by the value of the velocity of the back reaction (dissociation), which will increase as the conditional constant decreases. However, the retention factor  $k$  is directly proportional to the value of the conditional constant (eqn [8]). Therefore, to achieve optimum efficiency of separation, the conditional constants should be as low as possible, but not so low as to cause serious overlap of peaks close to

the solvent front. As most ligands arise from dissociation of an acid group, change in pH is the simplest way of changing the conditional constant and hence  $k$ . It should be noted that this property is very important for the chromatographic separation of metal cations, but not so critical when used for preconcentration or matrix isolation of groups of metal ions.

**Type of ligating atom** Nitrogen and oxygen are the most common ligating atoms in the chelating groups used in CIC. Sulfur-containing ones have been investigated, but are inherently unstable due to air oxidation. Nitrogen-ligating atoms can give slower kinetics than oxygen atoms with certain common metals, nickel being most notable. Even N, O, O chelators like iminodiacetic acid (IDA) give broad nickel peaks unless the conditional constant is very low and the nickel is close to the solvent front.

### Structural Properties of the Chelating Exchanger

**Conformational mobility of the bonded ligand** Chelating ion-exchangers having functional groups chemically attached as a monolayer to the surface through flexible long linkers will provide better selectivity and separation efficiency as they are more easily accessible to metal ions. On the other hand, chelating substrates formed by immobilizing ligands in micropores will be more sterically hidden, subsequently decreasing the kinetics of metal ion association.

**The distribution density of functional groups at the surface** A very high concentration (capacity) of functional groups can lead to nonuniform complexation at the surface of the chelating ion-exchanger. Perhaps a more important consideration is that close proximity of ligands allows the theoretical possibility of formation of  $ML_2$  and even  $ML_3$  complexes with much less favorable kinetics of dissociation, causing poor (broad and tailing) peak shapes in CIC. It should be noted that for some chelating substrates such as silica bonded IDA, due to thermodynamic considerations,  $ML_2$  and  $ML_3$  complexes are not formed at the typical low pHs used for separations.

It is interesting to note that, depending on the distribution and density of the functional groups, weak cation-exchangers with carboxylic and phosphonic acid functional groups could serve as chelating ion-exchangers as two or more groups in close proximity may be able to form chelate-related structures with metal ions, though this may have a bearing on peak broadening as discussed above.

**Pore size** The structure of the substrate can also affect the stoichiometry of complexes at the surface. In narrow pores the coordination of two attached ligands is much more probable.

## Main Types of Chelation Ion-Exchangers

Rigidity and mechanical stability of the substrate under conditions of high-performance liquid chromatography are important and microspherical particles of macroporous highly crosslinked PS-DVB or poly(metacrylate) and silica are well suited for CIC. There are three main methods of producing a chelating ion-exchange surface.

### Chemically Bonded

This is the most common approach to producing a chelating surface as can be seen from the selection shown in Table 1A. Although they are all capable of producing separations, only a small number appear to have sufficiently good kinetics for chromatographic separations, the most popular being IDA and aminophosphonic acid.

### Impregnation

Relatively large chelating dyestuff molecules can form an essentially permanent coating by becoming 'trapped' in the pores of the substrate. PS-DVB resins are the most successful for this mode as  $\pi$ - $\pi$  interactions between the aromatic rings of the dye and the resin help to hold the chelating molecule in place. Table 1B shows some representative examples of those used for chromatographic separations. Those containing the IDA group appear to give the best efficiency, though not as good as the chemically bonded type, presumably due to the chelating groups being more sterically hindered in the pore structure.

### Dynamic Coating

Dynamic coating or modification involves creating a chelating surface by having a ligand continuously present in the eluent. Conditions are chosen so that no permanent impregnation occurs, but rather a dynamic equilibrium is established between a sorbed layer of ligand on the surface of the substrate and the concentration of the ligand in the mobile phase. Due to the preferred adsorption of the ligand, its concentration at the surface is much higher than in the eluent, thus producing a chelation ion-exchange mechanism. Altering such parameters as the concentration of ligand in the eluent, mobile phase pH, and the nature of the stationary phase allows the dynamic

equilibrium to change, thus affecting metal selectivity. This is a relatively new approach and some representative examples are given in Table 1C. Although large molecules such as chelating dyestuffs have been successfully used in the dynamic mode for chromatographic separations, most work has concentrated on small molecules with aromatic groups such as dipicolinic acid.

## Practical Aspects of Chelation Ion-Chromatography

### Precolumn Systems with Common Chromatographic Equipment

The original and most widespread application of chelating ion-exchangers is in the selective adsorption of one or more metal ions of interest from diluted solutions followed by sensitive determination. The short columns or cartridges are not designed for the efficient chromatographic separation of metal ions, but rather for collection on the column before being swept off as a concentrated 'plug'. By this means matrix isolation and/or preconcentration can be carried out before further analysis online or offline. For CIC, one approach, as explained previously, is to use a chelating precolumn as part of an online IC system and can be considered as one constituent of the overall separation/determination process. Conventional ion-exchange columns, connected in series with the chelating column, are used for the analytical separation of metal ions before postcolumn reaction detection. The most common chelating columns are based on IDA or 8-hydroxyquinoline, bonded to controlled pore glass, silica, or PS-DVB resins. Some are available commercially, though many 'home made' columns are described in the literature. These systems have been used successfully to determine trace metals in a number of complex samples, though of necessity the set-up can be rather complex. One commercially available system, for example, involves three columns (the first one being the chelating ion-exchange column) several pumps, eluents, and switching valves.

### High-Performance Chelation Ion Chromatography

A relatively recent approach in CIC involves more efficient, small particle size substrates as the chelating surface. The use of these high-performance stationary phases means that reasonably fast analytical separations of groups of metal ions can be obtained similar to conventional high-performance ion-exchange. Matrix isolation is not normally required as the chelating column is relatively insensitive to concentrated salt solutions. Preconcentration, if necessary, can also

be carried out using a step pH gradient. Thus, matrix isolation, preconcentration, and analytical separation can be achieved using a single high-efficiency chelating column, removing the need for a complex multicolumn system as described in the previous section.

The sorption process controlling separation can be almost pure chelation or a combination of chelation and simple ion-exchange as discussed in detail in the section on chelation ion-exchange equilibria. A straightforward way of controlling the relative contribution of chelation and simple ion-exchange is

through the ionic strength of the eluent. Increasing the concentration of an alkali metal salt such as potassium nitrate in the eluent will suppress simple ion-exchange interactions. Concentrations as high as one molar have been used to achieve almost complete suppression of ion-exchange for many metal ions.

The chromatograms in Figures 1–6 were selected to show the kind of analytical separations and selectivities available for groups of metal ions for the three types of chelating surface: bonded,

**Figure 2** Isocratic separation of standard mixture of 14 lanthanides and yttrium on a 250 mm × 4 mm column, packed with 5  $\mu\text{m}$  silica IDA. Eluent:  $1.6 \times 10^{-2} \text{ mol l}^{-1} \text{ HNO}_3$  with  $0.5 \text{ mol l}^{-1} \text{ KNO}_3$ ; flow rate  $1.0 \text{ ml min}^{-1}$ ; column temperature  $65^\circ\text{C}$ ; sample volume  $20 \mu\text{l}$ , sample concentration of each metal was 4 ppm in 0.2%  $\text{HNO}_3$ . impregnated, and dynamically loaded. For many chelating substrates the selectivity factors for metal ions in simple eluents can vary over a large range. This means that to separate four or more metal ions isocratically in a reasonable time can be a problem. **Figure 1** illustrates this situation quite clearly for silica IDA columns, where a simple dilute nitric acid eluent can separate four relatively weakly retained metal ions, but the more strongly held metal ions such as copper or lead require complexing eluents and/or gradients to elute them more quickly. Although the application of gradients is more complex, gradients have the advantage of sharpening later eluting peaks and allowing on-column preconcentration if required. Two exceptions to this general situation have been found so far. The first involves aminophosphonate bonded silica (**Figure 3**) where eight common metal ions can be separated isocratically in

**Figure 6** Chromatogram showing the separation of six acid hydrolyzing metal ions on a dynamically coated column ( $100 \times 4.6$  mm ID), packed with  $5 \mu\text{m}$  PLRPS polystyrene divinylbenzene resin. Eluent,  $1 \text{ mol l}^{-1}$  potassium nitrate and  $0.1 \text{ mol l}^{-1}$  dipicolinic acid in  $0.5 \text{ mol l}^{-1}$  nitric acid. 16 min using dilute nitric acid eluent, though iron(III) is strongly retained under these conditions. The second exception concerns the separation of the lanthanides and yttrium on IDA bonded silica (Figure 2). The separation of such a large number of metals isocratically is possible because of the relatively small differences in stability constants and hence  $k$  values between the individual lanthanides. In contrast, this very difficult lanthanide separation is impossible to achieve isocratically by conventional ion-exchange in a realistic time frame and all published methods use gradients with complexing eluents.

### Detection in Chelation Ion Chromatography

The main mode of detection of eluted metal species is the same as that used in conventional high-performance ion-exchange chromatography, so the reader is referred to the Further Reading section for more detailed information. Essentially, postcolumn reactions involving colorimetric reagents are employed to achieve the highest sensitivity detection. 4-(2-pyridylazo)resorcinol (PAR) is the most commonly used colorimetric reagent, reacting sensitively with a wide range of metals. However, it should be pointed

out that lower limits of detection can be achieved using CIC compared to conventional IC separations. This is because many IC methods use strong complexing acids at relatively high concentrations in the eluents, which compete with colorimetric reagents such as PAR, reducing optimum sensitivity. In contrast, most CIC methods use either noncomplexing eluents or eluents containing relatively weak complexing acids.

## Applications

In this section, examples of applications involving high-efficiency CIC columns have been selected to demonstrate the wide range of complex samples analyzed using this technique (Table 2). The table is divided into three sections in terms of how the chelating substrate is formed, namely, bonded, impregnated, and dynamically coated. The insensitivity to ionic strength and special selectivity of these columns can be especially seen in the ability to analyze highly saline samples and digested sediment and mineral samples containing relatively enormous amounts of matrix metals. Figures 7–11 have been selected to illustrate some of the actual chromatographic separations obtained under these conditions.

## Isolation of Biopolymers

**P R Levison**, Pall Europe Ltd., Portsmouth, UK

## Introduction

Biopolymers, the so-called ‘building blocks of nature’, are found in all living matter be it of animal, microbial, or vegetable origin. Biopolymers include proteins (polymers of amino acids), genetic material (polymers of nucleic acids), glycoforms (carbohydrates and glycosylated molecules), metabolites, and other structural molecules. By their very sequence and chemical composition many biopolymers have an electrical charge and can therefore be fractionated by ion-exchange processes. This article briefly reviews the principles underlying biopolymer purification by ion exchange and addresses some of the process issues associated with their purification.

## Ion-Exchange Chemistries

Ion-exchange chromatography is routinely used for the separation of biopolymers at laboratory scale

through to process scale. Ion exchangers are available from a number of manufacturers each produced using their proprietary synthesis methods. For biopolymer separations there are typically four ionic functionalities available. In the case of anion exchange, there are so-called weak anion exchangers (WAX) often based on weak amines including aminoethyl, diethylaminoethyl, guanidoethyl, *p*-aminobenzyl, ECTEOLA, and polyethyleneimine, and strong anion exchangers often based on a quaternary amine. Examples of each functionality are represented in Figure 1.

The choice of anion exchanger is process dependent and for high pH applications, i.e., pH > 8.5 the more ionized grade, e.g., *N,N,N*-trimethyl-2-hydroxypropyl amine, would be recommended.

In the case of cation exchange there are so-called weak cation exchangers often based on a carboxylic acid and strong cation exchangers often based on a sulfonic acid. Examples of each functionality are represented in Figure 2.

Choice of cation exchanger is also process dependent but for low pH applications, i.e., pH < 4.5, the more ionized grades, e.g., sufoxyethyl or sulfo-propyl, would be recommended.

## Applications

In this section, examples of applications involving high-efficiency CIC columns have been selected to demonstrate the wide range of complex samples analyzed using this technique (Table 2). The table is divided into three sections in terms of how the chelating substrate is formed, namely, bonded, impregnated, and dynamically coated. The insensitivity to ionic strength and special selectivity of these columns can be especially seen in the ability to analyze highly saline samples and digested sediment and mineral samples containing relatively enormous amounts of matrix metals. ## Introduction

Biopolymers, the so-called ‘building blocks of nature’, are found in all living matter be it of animal, microbial, or vegetable origin. Biopolymers include proteins (polymers of amino acids), genetic material (polymers of nucleic acids), glycoforms (carbohydrates and glycosylated molecules), metabolites, and other structural molecules. By their very sequence and chemical composition many biopolymers have an electrical charge and can therefore be fractionated by ion-exchange processes. This article briefly reviews the principles underlying biopolymer purification by ion exchange and addresses some of the process issues associated with their purification.

## Ion-Exchange Chemistries

Ion-exchange chromatography is routinely used for the separation of biopolymers at laboratory scale

through to process scale. Ion exchangers are available from a number of manufacturers each produced using their proprietary synthesis methods. For biopolymer separations there are typically four ionic functionalities available. In the case of anion exchange, there are so-called weak anion exchangers (WAX) often based on weak amines including aminoethyl, diethylaminoethyl, guanidoethyl, *p*-aminobenzyl, ECTEOLA, and polyethyleneimine, and strong anion exchangers often based on a quaternary amine. Examples of each functionality are represented in Figure 1.

The choice of anion exchanger is process dependent and for high pH applications, i.e., pH > 8.5 the more ionized grade, e.g., *N,N,N*-trimethyl-2-hydroxypropyl amine, would be recommended.

In the case of cation exchange there are so-called weak cation exchangers often based on a carboxylic acid and strong cation exchangers often based on a sulfonic acid. Examples of each functionality are represented in Figure 2.

Choice of cation exchanger is also process dependent but for low pH applications, i.e., pH < 4.5, the more ionized grades, e.g., sufoxyethyl or sulfo-propyl, would be recommended.

**Figure 1** Chemical formulae for anion-exchange functional groups.

**Figure 2** Chemical formulae for cation-exchange functional groups.

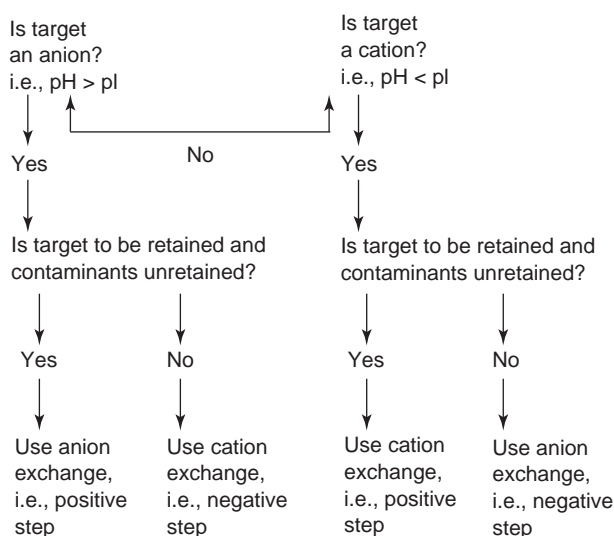

The charged functional groups are typically covalently bonded to an inert and insoluble support matrix often through an ether linkage. A number of support matrices are used traditionally based on polysaccharides such as agarose, cellulose, or dextran. More recently, polymeric and composite matrices have appeared, the selection often dictated by the nature of the chromatographic step.

## Media Selection

Media selection is perhaps the most challenging aspect of the development of the chromatographic separation. Media screening exercises are a useful avenue to pursue and there is enabling hardware available to facilitate parametric screening in an automated mode. However, rather than be faced with the task of screening in excess of 100 ion exchangers a preliminary desktop screen may be carried out to reduce the number of potential candidates. Factors such as the nature of the target molecule in terms of molecular weight and net surface charge, the nature of the contaminants, the conductivity of the feedstock, and both the upstream process and subsequent downstream process may impact on the selection of ion exchanger.

Ion exchangers can be used in either positive or negative chromatographic modes, i.e., target binds, impurities pass or target passes, impurities bind. This approach is summarized in **Figure 3**.

In order to effect purification the biopolymer-containing feedstream needs to be contacted with the ion

**Figure 3** Approaches to development of an ion-exchange chromatographic process.

exchanger. This process referred to as adsorption, which is kinetically limited, is an ionic process between adsorbent and adsorbate. This process operation must be carried out in a suitable contacting system. These are typically either column or batch stirred tanks and various designs exist. Several system configurations are available. Examples include use of axial or radial flow columns, fixed or variable volume, manual or automated packing/unpacking, use in packed bed, expanded bed, fluidized bed, or suspended bed, and magnetically coupled separations. The requirements of the chromatographic process itself and the adsorption kinetics that directly correlate with contact time may dictate the mode of contacting adsorbent and adsorbate. Following biopolymer adsorption, the adsorbent is typically washed to remove nonbound material. Biopolymers are next desorbed and eluted from the ion exchanger using either a change in pH or ionic strength. For similar reasons this desorption process, which again relies on an ionic interaction between adsorbate, counterion, and adsorbent, may be carried out under step or gradient conditions with the selection dictated by the process itself and the subsequent downstream operation.

Selection of anion or cation exchange will be dictated by many of these issues together with physicochemical parameters such as pH, pI, relative molecular mass, temperature, viscosity. The complex nature of naturally occurring biopolymer systems and the ability of biopolymers to adsorb to surfaces through several modes of interaction often results in incomplete desorption of adsorbate from the ion exchanger. It is well known that up to  $2 \text{ mol l}^{-1}$  NaOH is a suitable regenerant for ion-exchange media and will remove most, if not all, of these strongly

adsorbed species. It is important during media selection to develop a suitable regeneration strategy that will meet the quality requirements but without adverse impact on the chemical integrity of the adsorbent itself.

## Biopolymer Separations

While there are numerous biopolymer separations including proteins, nucleic acids, peptides, sugars, metabolites, etc., that have been published using ion-exchange cellulose at the laboratory scale, few process-scale separations are reported. By way of examples, the large-scale separations of hen egg-white proteins and the separation of immunoglobulin G from goat serum with anion-exchange celluloses have been reported and demonstrated to readily scale by up to 1000-fold.

These examples mentioned above used clarified feedstreams. Such separations are typically carried out using batch or column contactors and are well established. However, as the need for intensified and integrated processes has grown there has been a drive to position the ion-exchange steps earlier in the process and thereby reduce the complexity of upstream clarification-related processes, together with the cycle time and the overall operating costs.

One approach to achieve these objectives is the direct adsorption of the target from a particulate-containing feedstream. Over recent years the technique of expanded bed chromatography has emerged to address this very issue. By expanding an adsorbent bed with upward flow of the feedstream, bioparticulates (cells, cell debris, organelles, etc.) can pass relatively unimpeded through the enhanced bed voidage without seriously constraining the adsorption of target products to the stationary phase. This approach has been well documented for various biopolymer purifications including monoclonal antibodies, enzymes including xylanase, plasmid DNA, and other bioactive molecules such as endostatin. The technique demands the use of customized dense adsorbents in a specialized contactor requiring relatively sophisticated operating protocols.

An alternative approach is the technique of suspended bed chromatography. Here, ion exchangers and columns designed for packed bed operations may be used in alternative protocols. Briefly, adsorption is carried out in batch mode, and the resulting adsorbent suspension is filter collected/clarified in a conventional fixed bed contactor for washing and elution. This approach is enabled by the availability of pump-packed column chromatography systems. The technique was first demonstrated with a clarified

hen egg-white feedstock using anion-exchange cellulose and then used to directly isolate the intracellular enzyme glyceraldehyde-3-phosphate dehydrogenase from wet-milled Bakers' yeast also using anion-exchange cellulose. Although essentially a batch process, suspended bed chromatography could in principle be beneficially applied to the primary capture of biopolymers from unclarified fermentation broths, cell disruptates, and biological extracts provided that the inherent concentration of suspended solids did not compromise the characteristic adsorption, washing, and desorption procedures associated with this new technology.

Membrane-based adsorbers and monolithic phases are gaining a presence in the ion-exchange purification of biopolymers. These formats exploit the rapid binding kinetics and enable high volumetric flow rates to be achieved during operation. For the separation of small organic molecules the use of either liquid chromatography or polymeric resins is often favored. These techniques are preferred for reasons of speed, robustness, solvent compatibility, etc., but for charged organic molecules there is no reason, in principle, why ion exchange should not be used.

Peptides synthetically prepared or originating from protein hydrolysates can be separated on either cation or anion exchangers. For example, in the food and flavor industry fermentation of microorganisms has a role since several organisms produce natural organic acids that have commercial use. The organism *Propionibacterium acidipropionici* secretes propionic acid and *Clostridium acetobutyricum* secretes butyric acid, specialized products with added value and these have been shown to adsorb to anion exchangers. Such approaches may have application in the biotechnology industry particularly using a continuous removal approach such as expanded or suspended bed so feedback inhibition arising from high concentrations of bioproducts is minimized.

Nucleic acid purification is a growing area, for example, in applications of genomics and also the purification of plasmid DNA for gene therapy. Anion-exchange chromatography using packed beds, expanded beds, and magnetically coupled separations is established in this field often using the WAX products to aid desorption due to the high surface charge of the nucleic acid. The use of viral products for both gene therapeutics and vaccines offers scope for anion-exchange chromatography. These large particles typically have a negative charge and although generally excluded from the pores of the exchanger can be effectively purified by this means and industrial processes using such techniques are established.

Detailed examples of these applications are described in the articles cited in the Further Reading section.

## Isotope Separation

**Y Marcus**, The Hebrew University of Jerusalem, Jerusalem, Israel

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

Ion-exchange chromatography is able to combine the effects of many single-stage separations due to the small height of the equivalent theoretical plates, 0.1–10 mm. Hence, it can be used for the (partial) separation of isotopes for which the separation factors are of the order of 1.001 only. This method has been used for many elements, and in some cases, e.g., boron and uranium, has led to industrial isotope enrichment.

It is extremely difficult to separate isotopes by chemical means, although some of their properties are mass dependent. The differences in property are reflected in the equilibrium constants pertaining to the different isotopic species, corresponding to 0.1–10 J mol<sup>−1</sup> in Gibbs free energy. In order to achieve useful isotope separations it is necessary to multiply the single equilibrium effect many-fold and ion-exchange chromatography and related techniques are excellent methods for this purpose. In contrast to the equilibrium effect, the kinetic isotope effect and the difference in the diffusion coefficients between species in solution containing different isotopes have not found much use in isotope separation by ion

exchange. In solution the ions are solvated and the mass difference between the different isotopes of the ions becomes ‘diluted’ by the masses of the solvent molecules, so that this effect is much smaller than for the ‘bare’ ions.

Taylor and Urey were the first, in 1937, to separate isotopes (<sup>6</sup>Li and <sup>7</sup>Li as Li<sup>+</sup>, and <sup>14</sup>N and <sup>15</sup>N as NH<sub>4</sub><sup>+</sup>) by ion-exchange chromatography, using a zeolite cation exchanger. They employed a breakthrough as well as an elution process and found for lithium that <sup>6</sup>Li was enriched in the tailing edge of the band sorbed on the zeolite. A year later they reported that for potassium (<sup>39</sup>K and <sup>40</sup>K) it was the leading edge of the band in which the lighter isotope was enriched. The next significant report was that of Glueckauf, Barker, and Kitt, in 1949, who pointed out that an essential condition for the successful separation was the maintenance of sharp boundaries of the band sorbed on the ion-exchange column. They employed a polyfunctional cation-exchange resin, and again <sup>6</sup>Li was enriched in the rear edge of the band. Spedding, Powell, and Svec, in 1955, returned to the separation of the isotopes of nitrogen, this time on a synthetic polystyrene sulfonate (PSS) resin. The ion-exchange reaction was accompanied by a chemical equilibrium between ammonium ions and aqueous ammonia. The lighter isotope was enriched in the rear of the sharp band that was displaced a great many lengths along the resin column.

## Isotope Separation

**Y Marcus**, The Hebrew University of Jerusalem, Jerusalem, Israel

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

Ion-exchange chromatography is able to combine the effects of many single-stage separations due to the small height of the equivalent theoretical plates, 0.1–10 mm. Hence, it can be used for the (partial) separation of isotopes for which the separation factors are of the order of 1.001 only. This method has been used for many elements, and in some cases, e.g., boron and uranium, has led to industrial isotope enrichment.

It is extremely difficult to separate isotopes by chemical means, although some of their properties are mass dependent. The differences in property are reflected in the equilibrium constants pertaining to the different isotopic species, corresponding to 0.1–10 J mol<sup>−1</sup> in Gibbs free energy. In order to achieve useful isotope separations it is necessary to multiply the single equilibrium effect many-fold and ion-exchange chromatography and related techniques are excellent methods for this purpose. In contrast to the equilibrium effect, the kinetic isotope effect and the difference in the diffusion coefficients between species in solution containing different isotopes have not found much use in isotope separation by ion

exchange. In solution the ions are solvated and the mass difference between the different isotopes of the ions becomes ‘diluted’ by the masses of the solvent molecules, so that this effect is much smaller than for the ‘bare’ ions.

Taylor and Urey were the first, in 1937, to separate isotopes (<sup>6</sup>Li and <sup>7</sup>Li as Li<sup>+</sup>, and <sup>14</sup>N and <sup>15</sup>N as NH<sub>4</sub><sup>+</sup>) by ion-exchange chromatography, using a zeolite cation exchanger. They employed a breakthrough as well as an elution process and found for lithium that <sup>6</sup>Li was enriched in the tailing edge of the band sorbed on the zeolite. A year later they reported that for potassium (<sup>39</sup>K and <sup>40</sup>K) it was the leading edge of the band in which the lighter isotope was enriched. The next significant report was that of Glueckauf, Barker, and Kitt, in 1949, who pointed out that an essential condition for the successful separation was the maintenance of sharp boundaries of the band sorbed on the ion-exchange column. They employed a polyfunctional cation-exchange resin, and again <sup>6</sup>Li was enriched in the rear edge of the band. Spedding, Powell, and Svec, in 1955, returned to the separation of the isotopes of nitrogen, this time on a synthetic polystyrene sulfonate (PSS) resin. The ion-exchange reaction was accompanied by a chemical equilibrium between ammonium ions and aqueous ammonia. The lighter isotope was enriched in the rear of the sharp band that was displaced a great many lengths along the resin column.

The sustained Japanese effort in this field started with Kakihana and his co-workers in 1959, again with the separation of sodium isotopes. This group at the Tokyo Institute of Technology (TIT) and a few other Japanese groups have devoted considerable efforts to the separation of the isotopes of many elements by ion exchangers, contributing to the theory and the laboratory practice. Preparative-scale isotope separation by ion exchange has been reported mainly for the isotopes of boron,  $^{10}\text{B}$  and  $^{11}\text{B}$ , and uranium,  $^{235}\text{U}$  and  $^{238}\text{U}$ , including industrial implementation. The work at TIT continues, led by Okamoto and now by Fujii. More recently, a South Korean group led by Kim has also undertaken intensive studies of the ion-exchange separation of isotopes.

## Processes for Isotope Separation

### Breakthrough Process

The breakthrough process is the simplest for the separation of two solutes on an ion-exchange column. As the absorbed band travels down the column its front is depleted in the less well sorbed solute, whereas the other solute is enriched in this part of the band. The concentration profiles of the solutes in the effluent are S-shaped. Only the slight difference in the equilibrium constants  $K$  for the ion-exchange reactions of the light (subscript L) and heavy (subscript H) isotope ions (X) with the counterion of the resin (Y) is employed as in reaction [I]:

where R represents an equivalent of the fixed ion of the exchanger. The separation factor, i.e., the ratio  $\alpha = K_\text{L}/K_\text{H}$  is very near unity, and the elementary separation effect (see below)

$$\varepsilon = \alpha - 1 = (K_\text{L}/K_\text{H}) - 1 \quad [1]$$

is very small ( $\sim 10^{-5}$ ). Some of the early studies of the separation of isotopes by ion-exchange chromatography employed this process, e.g., the 1949 study of Gluekauf, Barker, and Kitt on the separation of lithium isotopes, where  $^7\text{Li}$  broke through first.

### Elution Process

In an elution process, a definite amount of the two solutes is sorbed as a band at the top of the ion-exchange column and a solution of an eluent is passed through the column to develop the chromatogram. In ideal cases of fast diffusion in the grains of the ion exchanger and uniform particle size, a symmetrical

bell-shaped (Gaussian) plot of the total concentration of the solute against the volume of eluent results. When the solutes are isotopes of a given ion their individual elution curves are slightly displaced along the abscissa, but a single overall elution curve is obtained, with enrichment of the one isotope in the front of the band (the less strongly sorbed isotope) and of the other in its rear (see Figure 1). For nonideal elution conditions the elution curve becomes skewed, the front being steeper and the rear showing trailing.

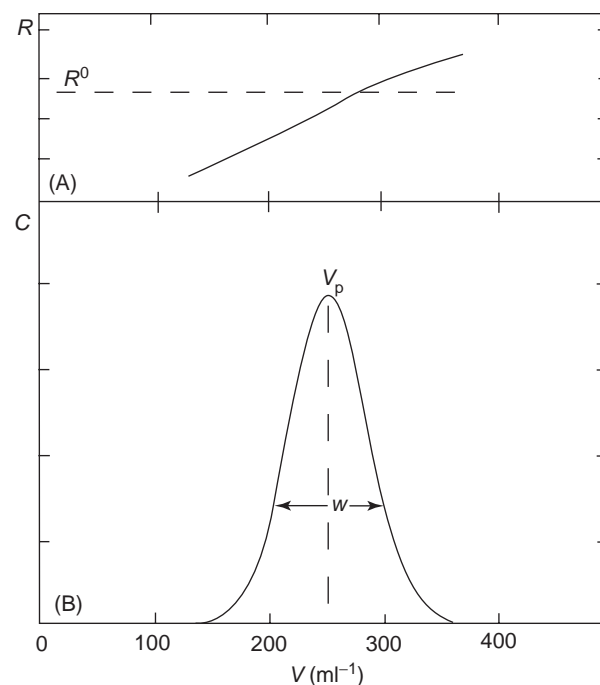

A special feature of the elution process (reaction [II]) is that it permits the superimposition of a complexing reaction with ligands L on the ion-exchange reactions [Ia] and [Ib]:

The separation factor is now

$$\alpha = (K_\text{L}/K_\text{H})(K_{n\text{L}}/K_{n\text{H}})^{\pm 1} \quad [2]$$

where the + sign in the exponent is used in the favorable case where the complexation works in the same direction regarding the isotopes as the ion-exchange reaction. This process has been used mainly for the determination of the separation factor for a given exchanger/eluent/isotope-pair system.

**Figure 1** Ideal elution curve from an ion-exchange column of a di-isotopic single solute ion. (A) The isotopic ratio  $R$  as a function of the elution volume  $V$ . (B) Total concentration  $C$  of the ion in the eluate as a function of  $V$ .

Since it is a batch process, and the band broadens due to longitudinal diffusion as it travels down the column, it is not suitable for preparative separations. An example of its use is the work of Aaltonen in 1972 on the separation of, say,  $^{88}\text{Sr}$  from  $^{87}\text{Sr}$  on a PSS resin of small grain size (400 mesh) with elution by  $\alpha$ -hydroxyisobutyrate solutions. The heavier isotope formed the more stable complex (the less well sorbed cation) and was enriched at the front of the band. A mathematical model for the elution separation of  $^{15}\text{N}$  from  $^{14}\text{N}$  by NaOH (converting  $\text{NH}_4^+$  in the cation exchanger to  $\text{NH}_3$  in the solution), based on the experimental results of Spedding and co-workers (1955), was recently presented by Fujii and co-workers (1997).

### Band Displacement Process

The band displacement process differs from the elution process (in which, too, the sorbed band is displaced) by providing for the self-sharpening of both edges of the band, so that the concentration

profile remains rectangular (see Figure 2). This is achieved by ensuring that the column ahead of the band has a counterion that is much less strongly sorbed than the isotopic ions and that the rear end of the band is displaced by ions that are much more strongly held. The first condition is met, for example, by the use of a cation exchanger in the hydrogen form and elution with a salt of a weak acid that removes the hydrogen ions effectively. The second condition is met by elution with a complexing agent combined with a counterion that is only weakly complexed, so that the strongly complexed isotopic ions travel down the column. Both conditions can, of course, be met with the same combination of reagents.

The work of Sakuma, Okamoto, and Kakihana is an example of the use of band displacement chromatography for the cation exchange separation of uranium isotopes, employing uranium(IV) sulfate and displacement with  $0.40 \text{ mol l}^{-1} \text{ MgSO}_4 + 0.02 \text{ mol l}^{-1} \text{ H}_2\text{SO}_4$ . At the rear end of the band, magnesium ions displace the uranium(IV) ions that form much stronger sulfate complexes as in reaction [IIIa]:

At the front edge of the band the uranium ions displace hydrogen ions that are bound as hydrogen sulfate anions as in reaction [IIIb]:

In both cases, the chemical association reactions work in the same direction for the isotopes as the cation-exchange reactions, resulting in an enhancement of the effect. The net isotope equilibrium is as in reaction [IV]:

and the rarer lighter isotope,  $^{235}\text{U}$ , is enriched at the rear edge of the band.

### Electromigration in a Column

The principle used for the counter-current ion-exchange isotope separation by electromigration in a column is the balancing of the hydraulic flow of the ions X, the isotopes of which are to be separated, by the opposite flow of ions Y in an electric field. The X ions should be the more strongly sorbed on the ion exchanger and the Y ions should be the more mobile ones in the field. A sharp boundary between the two kinds of ions is attained at some place in the column and is maintained there by the balancing of the flows. The steady passage of electric current is equivalent to movement of the sorbed band of X (which is actually

**Figure 2** Elution curve for self-sharpening band displacement of a di-isotopic solute ion on an ion exchange column. (A) The isotopic ratio  $R$  as a function of the distance  $x$  that the band was displaced. (B) Total concentration  $C$  of the ion as a function of  $x$ . For the other descriptors see the section on production of separated isotopes.

stationary) along the column, and this results in the separation of the isotopes.

The method was tested by Kobayashi, Fujii, and Okamoto in 1982 for the separation of X = calcium isotopes on a cation-exchange column with Y = lithium ions. The heavier calcium isotopes,  $^{42}\text{Ca}$ ,  $^{43}\text{Ca}$ ,  $^{44}\text{Ca}$ , and  $^{48}\text{Ca}$ , were enriched at the front of the sorbed band, and the lighter one,  $^{40}\text{Ca}$ , at the rear, when the band 'migrated' several meters.

### Electromigration in a Membrane

Electromigration experiments in a membrane did not use the counter-current technique; hence, the band moved along the membrane strip, and only short runs could be made. A longer membrane strip (up to 1 m), stored in the cathode compartment and slowly drawn out through the tetrachloromethane cooling bath and anode compartment, so as to keep the band stationary, constituted an improvement. As current is passed, the isotopes migrate at different rates that are proportional to the square root of the mass of the migrating particle: the isotopic ion together with its hydration shell. This shell is smaller in the ion-exchange membrane than in a homogeneous aqueous solution, yielding a small advantage to electromigration in the membrane. The preferred practice, which produces a sharp leading edge of the band, is to have a highly mobile ion in the membrane ahead of the band (hydrogen ions) and a slower ion in its rear.

Fujii and co-workers (1985) used such a membrane configuration to separate calcium isotopes with a migration length of 0.70 m for a  $0.5 \text{ mol l}^{-1}$   $\text{CaCl}_2$  feed solution, resulting in enrichment factors smaller than those achieved by electromigration on the column.

### The Elementary Separation Factor

In the following, the elementary separation factor,  $\varepsilon = \alpha - 1$ , pertains to the ratio of the lighter to the heavier isotopes, and is positive if the lighter one is enriched in the ion exchanger with respect to the feed solution, and negative when it is depleted. For the sake of comparison, values of  $10^4 \varepsilon$  are generally quoted, irrespective of the mass difference between the heavier and lighter isotopes. The values obtained for the absolute values,  $|10^4 \varepsilon|$ , range from 0.1 to 300 but are generally between 1 and 10. In the following,  $C^0$  is the total concentration of the isotopes in the feed solution,  $q$  is the amount sorbed per unit mass of exchanger,  $R$  is the isotopic ratio ( $R^0$  initially), the enrichment is  $R/R^0 = (C_L/C_H)/(C_L^0/C_H^0)$  for a volume  $V$  of eluting or displacing solution passed through the ion-exchange column of length  $L$ , having  $N$  equivalent theoretical plates of height  $H$  ( $H = \text{HETP} = L/N$ ).

### From Breakthrough or Elution Curves

Glueckauf and coworkers (1949) showed that for breakthrough experiments, the important quantities are the relative depletion  $\eta$  of the slower moving, more strongly sorbed, isotope (subscript s):

$$\eta = (C_s^0 - C_s)/C_s^0 \quad [3]$$

and its slope with respect to the elution volume  $V$ ,  $\eta' = (\partial\eta/\partial V)V_t$ , with  $V_t$  being the threshold (breakthrough) volume. The final expression is

$$\varepsilon = (\pi\eta^2/4V\eta')[1 + (\pi\eta/4) + (5\pi^2\eta^2/64)] \quad [4]$$

For elution experiments (Figure 1) Glueckauf showed (1958) that  $\varepsilon$  is obtained from the enrichment, if the number of equivalent theoretical plates  $N$  is large and known:

$$\ln(R/R^0) = N\varepsilon(1 - V/V_p) \quad [5]$$

where  $V_p$  is the mean (for the two isotopes) of the peak elution volume. If  $w$  is the width of the elution peak at  $1/e$  of its height, a good approximation of  $N$  is  $N \approx 8(V_p/w)^2$ . This method has been frequently employed in recent years.

### From Band Displacement Data

The elementary separation factor is obtained in band displacement experiments from data on fractions  $i$  in the leading and tailing parts of the displaced band when it is finally eluted (see Figure 2). Let  $f_i$  be the total amount of the isotopic ions in the  $i$ th fraction,  $R_i$  be the isotopic ratio in this fraction, and  $Q$  the total exchange capacity of the exchanger column. It is assumed that in the region of the sorbed band on the ion exchanger the total concentration of the ion in the exchanger and in the solution in equilibrium with it are constant, the only net effect being the counter-current movement of the isotopes. Then,

$$\varepsilon = \sum f_i(R_i - R_0)/QR_0(1 - R_0) \quad [6]$$

The value of  $\varepsilon$  should be independent of the number of fractions included in the sum in eqn [6], and whether the leading or tailing parts of the eluate are analyzed. This independence was found in practice.

### Variables Affecting the Separation Factor

The only way that isotopes of a given ion can be separated on an ion exchanger is by ensuring that the different isotopes have different properties in the exchanger phase and in the external-solution phase. The way to do this is by (1) causing the environments

in the exchanger and the solution to be very different, and even better by (2) causing different species of the ions to be present in the two phases.

The cross-linked ion-exchange resin has generally lower water content than the external solution, and the water is less structured in the exchanger. If the external solution is dilute in electrolytes, these differences are enhanced with increasing cross-linking of the resin. Further enhancement of the differences can be achieved by the use of mixed solvents. The effects of cross-linking (e.g.,  $10^4\epsilon$  rising from 6 to 38 for lithium as the cross-linking X of the PSS resin changed from 2% to 24% divinylbenzene (DVB)) and solvent composition indeed confirm that the isotopes are hydrated slightly differently.

It is noteworthy that under suitable conditions, if the electrolyte concentration in the external (eluting) solution is raised, reversals in the sign of  $\epsilon$  are observed. Such a reversal was observed for calcium isotopes,  $\epsilon$  changing from negative to positive as the concentration of the eluting acid, HCl or HClO<sub>4</sub>, increased from 2.5 to 9.0 mol l<sup>-1</sup> with a 12% DVB PSS resin. A reversal of the sign of  $\epsilon$  can also be achieved by suitable choice of the displacing counterion. For chlorine isotopes,  $\epsilon$  was positive for elution with nitrate and negative for elution with fluoride.

Less drastic effects on the magnitude of  $\epsilon$  than the reversal of its sign were observed in many cases on changes of the concentration of the eluent or the nature of the counterion. An increase in the temperature was generally accompanied with a decrease of  $|\epsilon|$ . This was explained by the lowered structure of the water in the external solution, making it more similar to the internal water in the exchanger. However, in some cases it is advantageous to work at an elevated temperature, in order to assure rapid diffusion and attainment of equilibrium, decreasing the HETP, even at the expense of the separation factor.

The dependence of  $|\epsilon|$  on the mass difference  $\Delta m$  was studied for several multi-isotopic elements and in general a proportionality of  $|\epsilon|$  to  $\Delta m$  was found. For instance,  $10^4\epsilon$  is nearly twice as large for <sup>40</sup>Ca/<sup>48</sup>Ca separation (8.7) than for <sup>40</sup>Ca/<sup>44</sup>Ca (4.7) and about four times larger for <sup>84</sup>Sr/<sup>88</sup>Sr separation ( $0.97 \pm 0.07$ ) than for <sup>87</sup>Sr/<sup>88</sup>Sr ( $0.21 \pm 0.04$ ).

## Production of Separated Isotopes

It is clear that the larger the elementary separation factor,  $\epsilon$ , and the number of equivalent theoretical plates,  $N$ , of the ion-exchange column are, the higher

is the isotope enrichment that can be achieved. As Kakihana had shown in 1980, there are some further factors that have to be considered for preparative-scale isotope separation (enrichment). Band displacement chromatography has proved to be the most effective method for isotope enrichment by ion exchange, hence this is considered in the following (Figure 2). Suppose that a sharp-edged band consisting of the two isotopes is formed on the column, with the front of the band enriched in the heavier isotope after some displacement. When its mole fraction at the front of the band reaches the value desired for the product,  $R_H^P$ , material is withdrawn from the band. Let the start-up time  $t_s$  be the time between the start of the displacement and the production stage, given approximately by

$$t_s = [1 + \epsilon(1 - R_H^0)]\Delta R_H / \eta \epsilon v_b k_e \quad [7]$$

where  $\Delta R_H = R_H^P - R_H^0$ ,  $\eta = R_H^0(1 - R_H^P)/(1 + \alpha_v/d)$ ,  $\alpha_v$  is the void fraction of the column,  $d = (1 - \alpha_v) C_{\text{resin}}/C_{\text{solution}}$ . Also,  $v_b$  is the rate of band displacement: if the linear velocity of the eluting solution is  $v_e$ , then  $v_b = v_e/(\alpha_v + d)$ . Finally,  $k_e$  is the 'slope coefficient', which is inversely proportional to the HETP, and equals the difference in the rate of displacement of the two isotopes divided by the difference in their diffusion coefficients:  $(v_H - v_L)/(D_H - D_L)$ . The slope coefficient should be maximized. The width of the enriched zone  $\Delta x_e$  (Figure 2) is approximately

$$\Delta x_e = (l/k_e) \ln(\Delta R_H/A_e) \quad [8]$$

where the 'enrichment coefficient'  $A_e$  is proportional to  $\exp(k_e \kappa_e t) \exp(k_e x_p)$ , and where  $\kappa_e = (v_H D_H - v_L D_L)/(D_H - D_L)$ , and  $x_p$  is the distance from the origin at which  $\Delta R_H$  starts to deviate from 0. The rate of growth of the enriched zone is given approximately by  $d\Delta x_e/dt = \eta \epsilon v_b / \Delta R_H$ . Finally, the maximal rate of production per unit time per unit band volume, if the product is removed continuously, is approximately

$$U^P = C^0 (d\Delta x_e/dt) 2\Delta x_e \quad [9]$$

As an example, the enrichment of <sup>10</sup>B from its initial  $R_L^0 = 0.198$  to a product mole fraction of  $R_L^P = 0.5$  for a feed concentration of  $C^0 = 1 \text{ mol l}^{-1}$  and  $10^4\epsilon = 10$  may be considered. For a band displacement rate of  $v_b = 10 \text{ cm h}^{-1}$  and a typical slope coefficient  $k_e = 0.1 \text{ cm}^{-1}$  the start-up time would be  $t_s \sim 10^3 \text{ h}$ , the width of the enriched zone would be  $\Delta x_e \sim 20 \text{ cm}$ , and its rate of growth  $d\Delta x_e/dt \sim 0.005 \text{ cm h}^{-1}$ . The maximal rate of production of the 50% enriched <sup>10</sup>B would be  $U^P \sim 1 \text{ kg m}^{-3} \text{ h}^{-1}$ .

In another analysis of the band displacement method by Obermoller and White in 1991, applied to the anion-exchange redox method for uranium isotope separation (see below), the optimal length of the displaced band was determined to be  $L = 1.313HN^{1/2}$ . The relative concentration of the enriched isotope in the product is then  $1 + 0.551\epsilon N^{1/2}$ .

## Isotopes of Individual Elements

### Overview

Isotope separation by ion exchange has been applied to many elements, as is seen in Table 1. Obviously, mainly elements that have at least two naturally occurring isotopes have been studied, although in a few cases radioactive isotopes (e.g., for sodium:  $^{22}\text{Na}$  and  $^{24}\text{Na}$ ) have been included in the studies. Most of the results are summarized in Table 2, with more detailed description being accorded to some of the more intensely studied elements.

### Alkali Metals

**Lithium** Many of the earlier studies dealt with lithium, reasoning that the large relative mass difference  $\Delta m/m$  of 1/7 should help the separation. It was later realized that  $\Delta m/m$  is much smaller, since it is the hydrated ions (with  $m \gg 7$ ) that play their roles in the solution and the exchanger according to reaction [I]. In all the cases studied,  $^6\text{Li}$  was enriched in the ion exchanger. With PSS cation exchangers and elution with strong acids (HCl) or their salts, only relatively low values of  $10^4\epsilon$ , up to 40, were achieved, with  $d\epsilon/dX > 0$  ( $X$  denoting the degree of cross-linking) and  $d\epsilon/dT < 0$ . When a zeolite or a weakly acid exchanger were used and the base LiOH or a salt of a weak acid, such as acetic acid, were employed for elution, making use of reaction [III], higher values of  $10^4\epsilon$  were achieved, up to 220 in favorable cases (e.g., presence of 20% acetone). With

the inorganic exchanger  $\text{HNbO}_3$  a value of  $10^4\epsilon = 430$  and with an azacrown resin even  $10^4\epsilon = 680$  were recently reported, but the elution was slow. Electromigration in a cation-exchange membrane led to  $d\epsilon/dT > 0$  and  $d\epsilon/di > 0$  ( $i$  denoting the current density),  $10^4\epsilon \sim 200$  being achieved at high  $i$  (Table 2). (Table 2 also provides information on sodium, potassium, and rubidium.)

### Alkaline Earth Metals

**Magnesium** Recent work by Kim, using either hydrous  $\text{MnO}_2$  or a Merrifield peptide anchored azacrown resin exchanger provided separation between  $^{24}\text{Mg}$ ,  $^{25}\text{Mg}$ , and  $^{26}\text{Mg}$  with  $10^4\epsilon/\Delta m$  of  $\sim 110$  (Table 2).

**Calcium** Many studies have been devoted to this element, since here again  $\Delta m/m$  values up to  $8/40 = 1/5$  were expected. The values of  $\epsilon$  were, indeed, proportional to  $\Delta m$ , but not so large. This is mainly because on elution from a PSS cation exchanger, where only equilibria [I] operate,  $d\epsilon/dC_{\text{eluent}} < 0$ , so that  $\epsilon = 0$  is passed when the concentration of the eluent is increased. Typical values of  $10^4\epsilon/\Delta m$  for dilute eluents ( $1.5 \text{ mol l}^{-1}$  HCl,  $\text{HNO}_3$ ,  $\text{HClO}_4$ , LiCl) are 0–0.6, for concentrated eluents ( $\sim 9$ – $12 \text{ mol l}^{-1}$ ) these values are  $-2.1$  to  $-3.0$ . Elution with a complexing eluent,  $\alpha$ -hydroxy isobutyrate, from a PSS resin, adding equilibria [III], did not produce remarkably large separations,  $10^4\epsilon/\Delta m = 1.2$ . Some use of a chelating cation exchange resin was made, yielding the highly negative  $10^4\epsilon/\Delta m = -10.2$ . Electromigration in a PSS cation-exchange column led to positive  $\epsilon$  values, increasing with the concentration of the  $\text{CaCl}_2$  feed solution, with  $10^4\epsilon/\Delta m = 1.8$  at a  $0.5 \text{ mol l}^{-1}$  feed. However, electromigration in a PSS membrane led to negative  $\epsilon$  values,  $10^4\epsilon/\Delta m = -1.26$  at  $20^\circ\text{C}$  with  $d\epsilon/dT < 0$  (Table 2). (Table 2 also provides information on beryllium and strontium.)

**Table 1** Periodic chart of the ion-forming elements, showing in bold the elements for which their natural isotopes were separated by ion exchange, in *italics* the elements for which radioactive isotopes were so separated, and in underline the elements that have only a single natural isotope. For many elements naturally occurring isotopes could still be separated by means of ion exchange as is evident

## Other Metals

**Yttrium, neodymium, samarium, europium, and gadolinium** See Table 2.

**Copper and iron** Electron exchange on an anion exchange resin between Cu(I) and Cu(II) for  $^{63}\text{Cu}/^{65}\text{Cu}$  separation and between Fe(II) and Fe(III) for  $^{56}\text{Fe}/^{57}\text{Fe}$  separation in chloride media were recently reported and yielded  $10^4\epsilon$  values of -3.8 and -2.5, respectively, at room temperature with  $|10^4\epsilon| > 0$ .

**Uranium** A great deal of effort has been accorded to the separation of the isotopes of uranium with ion exchangers. In 1983, Marcus summarized the results, and little further work has been done since then. Uranium(IV) showed very small enrichment of  $^{235}\text{U}$  in the resin, with  $10^4\epsilon < 1.0$  for both cation and anion exchangers and a variety of eluents. Uranium(VI), as the uranyl ion  $\text{UO}_2^{2+}$ , showed somewhat larger effects,  $^{235}\text{U}$  enriching in the solution. A good correlation was found between the enrichment factor and the asymmetric stretching frequency  $\nu_3$  of the

$\text{O}=\text{U}=\text{O}$  bonds:  $10^4\epsilon = -0.046[960 - (\nu_3/\text{cm}^{-1})]$ , leading to as high a value as  $10^4\epsilon = -3.4$  for carbonate as eluent, see Table 2.

The most promising procedure for the separation of the isotopes of uranium is to superimpose a redox reaction between U(IV) and U(VI) on the ion exchange and complexation reactions. This generally requires a catalyst for its implementation on a cation-exchange resin (with dilute HCl), but the medium used for the anion-exchange mode of operation,  $>4 \text{ mol l}^{-1}$  HCl, is itself the catalyst. In a cation exchanger, a band of green U(IV) is sorbed on the purple Ti(III)-form of the resin, and is displaced by the yellow Fe(III). At the front of the band the uranyl cation is reduced and the quadruply charged U(IV) displaces the doubly charged Ti(IV) from the resin fixed ion,  $\text{R}^-$  as in reaction [Va]:

At the back of the band the U(IV) is re-oxidized to the uranyl ion (reaction [Vb]) that is displaced by the

better sorbed  $\text{Fe}^{3+}$ :

In an anion exchanger similar reactions take place, but with chloro-complexes of the titanium, iron, and uranium at the respective oxidation states participating: at the front reaction [VIa] and at the rear reaction [VIb]

With the cation exchanger  $10^4\epsilon = -7$  could be achieved in elution experiments, with the anion exchanger  $10^4\epsilon = 7$  in band displacement experiments. More recently this technique was employed for the separation of  $^{232}\text{U}$  and  $^{234}\text{U}$  from  $^{238}\text{U}$  with  $10^4\epsilon/\Delta m$  of  $\sim 4$ . See Table 2 for further information.

Electromigration experiments yielded disappointing results: with a cation-exchange membrane  $10^4\epsilon = -0.8$  was the maximal effect obtained. (Table 2 also provides information on zirconium, cobalt, and tin.)

### Nonmetals

**Boron** Boric acid is sorbed on an anion-exchange resin, whether weakly basic (in free base form) or strongly basic (in halide, X, preferably fluoride, form), with  $^{10}\text{B}$  enriched in the sorbed  $\text{B}(\text{OH})_4^-$  or  $\text{BX}(\text{OH})_3^-$  and  $^{11}\text{B}$  in the aqueous  $\text{H}_3\text{BO}_3$  species. Elution can take place with water, so that no regeneration is required. The separation factor depends only slightly on the resin basicity ( $10^4\epsilon = 130$  for a weak base resin, 100 for F-form strong base resin at room temperature for a  $0.1 \text{ mol l}^{-1}$  feed solution) and the temperature, but  $d\epsilon/dC_{\text{boron}} < 0$ . No isotope enrichment was found with a cation-exchange resin.

**Nitrogen** Experiments by Spedding in 1955 showed that for an X-12 PSS cation exchanger the equilibrium between aqueous ammonia and ammonium ions yielded  $10^4\epsilon = -257$  for  $^{14}\text{N}$  relative to  $^{15}\text{N}$ . Continued interest in this separation has not provided for substantially larger  $|10^4\epsilon|$  values in more recent years, although an X=30 porous PSS resin was employed. Large negative values were also obtained when the solution contained acetone or ethanol, and a small positive value of  $d\epsilon/dX$  was observed. Smaller values of  $10^4\epsilon$  ( $-70$  and  $-90$ ) were obtained when the ammonia was equilibrated not with the proton of the strongly acidic exchanger (to form ammonium ions) but with doubly charged metal ions,  $\text{Ni}^{2+}$  and  $\text{Mg}^{2+}$  (to form the hexamine complexes); see Table 2. (Table 2 also provides information on hydrogen, carbon, and sulfur and chlorine.)

## Introduction

Ion-selective electrodes (ISEs) are electroanalytical sensors whose signals depend on the activities of ions in solution and exhibit a certain degree of selectivity for particular ionic species. The operation of classical ISEs is based on direct measurement of a single membrane potential at zero net current. At present, ISEs also include electrodes containing two or more membranes and/or highly selective biochemical systems, and semiconductor sensors. The range of chemical species sensed is thus greatly broadened, involving various nonionic compounds and some gases. The selectivity is also improved.

The history of ISEs is quite long – almost one century – and involves three distinct stages: 50 years of gradual development of the glass pH electrode; the period of rapid development of various types of ISE starting in the late 1950s and ending in the beginning of the 1980s; the present period during which the field of ISEs is being perfected technically with emphasis on miniaturization and the range of highly specialized ISEs is being extended (primarily those selective for biologically, medically, and environmentally important analytes). However, no qualitatively new principle has recently been proposed. The theoretical background has been developed gradually (by, e.g., Nikolskii and Eisenman) and its present state was completed during the 1970s. At present, efforts are primarily directed toward gathering of highly scattered information and unification and standardization

of experimental approaches and routine analytical procedures, as reflected, e.g., in the activities of the International Union of Pure and Applied Chemistry.

The oldest and still the best and most widely used ISE is the glass pH electrode invented as early as in 1906 by Cremer and in 1909 by Haber and Klemensiewicz. It became a standard laboratory tool during the 1930s. Early attempts at constructing glass electrodes sensitive to ions other than hydroxonium ion and electrodes with membranes of materials other than glass were unsuccessful. Only in the late 1950s did practically useful glass electrodes appear that were sensitive to the alkali metal, ammonium, and silver ions; however, they are no longer used. Around 1960, Pungor and co-workers developed electrodes with membranes of silver halide dispersed in a silicone rubber matrix and sensitive to the corresponding halides. Frant and Ross described the highly successful fluoride ISE with a lanthanum fluoride single-crystal membrane in 1966. The first ISE with a liquid membrane appeared in 1967 (Ross).

The versatility of ISEs was enhanced considerably by the introduction of membranes containing neutral ion carriers (ionophores). The first ISE of this type, with a membrane containing valinomycin and selective for potassium ions, was described by Štefanac and Simon in 1966. There are many liquid chemical systems that interact highly selectively with ions through, e.g., ion exchange, ion association, or solvent extraction. Practically useful ISEs based on these systems and on neutral ionophores have been obtained due to the gradual perfection of the technology of plasticized poly(vinyl chloride) (PVC) matrix membranes.

If a substance that is not sensed by any ISE undergoes a selective (bio)chemical reaction producing or consuming suitable ions, then it can be determined indirectly by monitoring these ions with an ISE. The selective (bio)chemical system is usually directly

attached to the ISE membrane. In this way, sensors have been obtained for acidic gases. A great variety of enzymatic and immunochemical sensors for many important organic compounds have been developed on this principle.

The membrane potentials can also be measured indirectly, if the membrane is fixed on the surface of a field-effect transistor (FET) from which the metallic gate has been removed. The electric current passing between the source and drain of the FET is then controlled by the membrane potential. The first sensor of this type [ion-selective FET (ISFET) or chemically sensitive FET (CHEMFET, CSFET)] was described by Bergveld in 1970 and the field has been developed primarily by Janata and co-workers and Japanese researchers.

## Principles

At the interface of two phases that contain electrically charged species (ions, electrons, holes, or dipoles), a potential difference develops. In equilibrium, the electrochemical potentials,  $\tilde{\mu}_i$ , of phases 1 and 2 are equal for all the charged species present. Hence, for the  $i$ th species,

$$\tilde{\mu}_i(1) = \tilde{\mu}_i(2) \quad [1]$$

Assuming that the chemical properties of the phases are independent of the electrical charges present, which is justified in work with ISEs, eqn [1] can be rewritten in the form:

$$\begin{aligned} \mu_i^\circ(1) + RT \ln a_i(1) + z_i F \varphi(1) \\ = \mu_i^\circ(2) + RT \ln a_i(2) + z_i F \varphi(2) \end{aligned} \quad [2]$$

where  $\mu^\circ$  are standard chemical potentials,  $a_i$  is the activity of the  $i$ th species that carries  $z_i$  elementary charges,  $\varphi$  is the internal potential of the phase, and the other symbols have their usual significance. The potential difference at the interface is thus given by

$$\begin{aligned} \Delta\varphi = \varphi(2) - \varphi(1) &= \frac{\mu^\circ(1) - \mu^\circ(2)}{z_i F} + \frac{RT}{z_i F} \ln \frac{a_i(1)}{a_i(2)} \\ &= \text{const.} + \frac{RT}{z_i F} \ln \frac{a_i(1)}{a_i(2)} \end{aligned} \quad [3]$$

Therefore, when the activity of the  $i$ th component in one phase is known or is, at least, constant, then the activity of the  $i$ th component in the other phase can be found from the  $\Delta\varphi$  value.

The  $\Delta\varphi$  value cannot be measured directly. However, a phase that selectively exchanges charged species with solution on the basis of ion exchange, ion association, complexation, solvent extraction, adsorption, etc., can be placed in the form of an electrochemical membrane between the sample solution and a standard solution.

Two reference electrodes can then be immersed in the two solutions and the electromotive force (e.m.f.) measured in this electrochemical cell. The measured value consists of liquid junction potential(s), which can be maintained constant within a certain experimental error by maintaining a constant, relatively high ionic strength and a suitable composition of the solutions, and the interfacial potential differences at the sides of the membrane adjacent to the sample and standard solutions. As the potential difference between the membrane and the standard solution is constant, the overall change in the e.m.f. corresponds to the change in the composition of the sample solution.

The ISE membrane thus behaves as a permselective membrane and the signal measured is given by the Donnan potential, which depends on the selectivity of the interfacial interaction, given by the equilibrium constants of the interactions of the membrane with the analyte(s) and interferents. Moreover, a diffusion potential develops across the membrane, as charge is passed on the passage of ions between the solution and the membrane.

Therefore, the voltage value measured in a cell containing an ISE can be expressed in terms of the Nikolskii equation:

$$E = E_0 \pm \frac{RT}{z_i F} \ln(a_1 + K_{12}^{\text{Pot}} a_2) \quad [4]$$

where  $E_0$  comprises all the constant terms in the cell voltage,  $a_1$  is the activity of the analyte, and  $z_i$  its charge,  $a_2$  is the activity of an interferent and  $K_{12}^{\text{Pot}}$  is the coefficient of selectivity for determination of analyte 1 in the presence of interferent 2.

The coefficient of selectivity involves the effect of the equilibrium constant,  $K_{\text{eq}}$ , of the selective interaction of the analyte with the membrane, and of the mobilities,  $U$ , of the analyte and the interferent within the membrane. There are two important classes of membrane: (1) those with fixed exchange sites, i.e., solid ion exchangers or solids with fixed adsorption sites; (2) membranes with mobile exchange sites, i.e., liquids containing ion-exchange sites (liquid ion exchangers), liquids with neutral ion carriers, solvent extraction systems, liquids containing ion association agents, etc. For group 1, the selectivity coefficient is

$$K_{12}^{\text{Pot}} = \frac{U_2}{U_1} K_{\text{eq}} \quad [5]$$

For group 2, the situation is more complicated and two limiting cases can be distinguished: (a) with completely dissociated systems of mobile exchange sites,

$$K_{12}^{\text{Pot}} = \frac{U_2 D_2}{U_1 D_1} \quad [6]$$

where  $D$  is the distribution coefficient between the solution and the membrane; (b) with strongly associated systems the equation

$$K_{12}^{\text{Pot}} = \frac{U_{2S}D_2}{U_{1S}D_1} \quad [7]$$

where  $U_{1S}$  and  $U_{2S}$  are the mobilities of the associates, holds for highly mobile sites and the equation

$$K_{12}^{\text{Pot}} = \frac{(U_2 + U_S)D_2}{(U_1 + U_S)D_1} \quad [8]$$

where  $U_S$  is the solvent mobility, holds for exchange sites of low mobility.

With neutral ion carriers, the coefficient of selectivity is given by

$$K_{12}^{\text{Pot}} = \frac{U_{2S^+}D_{2S^+}K_{2S^+}}{U_{1S^+}D_{1S^+}K_{1S^+}} \quad [9]$$

where  $U$  are the mobilities of the complexes,  $D$  their distribution coefficients, and  $K$  their stability constants.

The dependence of the ISE potential on the analyte activity thus has the shape depicted in Figure 1. Some typical values of the selectivity coefficient are given in Table 1.

**Figure 1** Typical ISE calibration curves: 1, curve in the absence of the interferents; 2 and 3, curves in the presence of the interferents (curve 3 corresponds to a higher interferent concentration).

## Basic Electrode Types

As indicated in the previous section, there are two large groups of ISEs, those with fixed ion-exchange sites and the other with mobile exchange sites, irrespective of the kind of interaction underlying the exchange of ions.

The first group includes ISEs with solid membranes, consisting of glass, single crystals, polycrystalline materials, or a matrix of polymer containing particles of a polycrystalline active materials

**Table 1** Some important values of the selectivity coefficient

Analyte	ISE membrane type	Interferents	$\log K_{12}^{\text{Pot}}$
$\text{H}^+$	Glass	$\text{Na}^+$	$\sim -12$
$\text{Cl}^-$	$\text{AgCl}$ precipitate	$\text{CrO}_4^{2-}$	$-4.3$
		$\text{AsO}_4^{3-}$	$-3.5$
		$\text{CrO}_4^{3-}$	$-4.3$
		$\text{CO}_3^{2-}$	$-4.3$
		$\text{PO}_4^{3-}$	$-4.3$
$\text{Br}^-$	$\text{AgBr}/\text{Ag}_2\text{S}$	$\text{Cl}^-$	$-3.0$
		$\text{I}^-$	$+3.0$
		$\text{SCN}^-$	$-3.0$
		$\text{S}^{2-}$	$+10.0$
$\text{I}^-$	$\text{AgI}$ precipitate	$\text{Br}^-$	$-4.0$
		$\text{Cl}^-$	$-5.4$
		$\text{F}^-$	$-5.3$
		$\text{SCN}^-$	$0.0$
		$\text{SO}_4^{2-}$	$-5.4$
		$\text{NO}_3^-$	$-5.0$
$\text{S}^{2-}$	$\text{Ag}_2\text{S}$	$\text{CN}^-$	$-3.2$
		$\text{I}^-$	$-7.8$
		Other	$-10.7$
$\text{F}^-$	$\text{LaF}_3$ single crystal	$\text{OH}^-$	$-1.0$
		Other	$-3.0$
$\text{NO}_3^-$	$\alpha$ -Phenanthroline (substituted), complex with $\text{Ni}^{2+}$	$\text{ClO}_4^-$	$+3.0$
		$\text{I}^-$	$+1.3$
		$\text{ClO}_3^-$	$+0.3$
		$\text{Br}^-$	$-0.9$
		$\text{SH}^-$	$-1.4$
		$\text{NO}_2^-$	$-1.4$
		$\text{CN}^-$	$-2.0$
		$\text{HCO}_3^-$	$-2.0$
$\text{NH}_4^+$	Nonactin/monactin	$\text{Li}^+$	$-2.4$
		$\text{Na}^+$	$-2.7$
		$\text{K}^+$	$-0.9$
		$\text{Rb}^+$	$-2.4$
		$\text{Cs}^+$	$-2.3$
		$\text{Ca}^{2+}$	$-3.8$
		$\text{H}^+$	$-1.8$
$\text{K}^+$	Valinomycin + quaternary ammonium salt in dioctylphthalate	$\text{Li}^+$	$-4.0$
		$\text{Na}^+$	$-3.5$
		$\text{Rb}^+$	$+0.5$
		$\text{Cs}^+$	$-0.4$
		$\text{Mg}^{2+}$	$-5.1$
		$\text{Ca}^{2+}$	$-4.4$
		$\text{H}^+$	$-4.4$
$\text{Ca}^{2+}$	An acyclic, lipophilic neutral ionophore	$\text{Na}^+$	$-5.0$
		$\text{K}^+$	$-5.2$
		$\text{Mg}^{2+}$	$-5.1$
		$\text{H}^+$	$0.0$

**Figure 2** Basic types of ISE: (A) glass electrode; (B) electrode with a solid homogeneous or heterogeneous membrane; (C) classical liquid membrane electrode; (D) electrode without internal solution (all-solid-state electrode); (E) coated-wire electrode. 1, Internal standard solution; 2, internal reference electrode (Ag/AgCl); 3, membrane; 4, glass or plastic body of the electrode; 5, reservoir of the electroactive substance solution; 6, solid-state contact; and 7, metal wire.

(Figures 2A and 2B). The single-crystal membranes (e.g.,  $\text{LaF}_3$  doped with europium(II) in the fluoride ISE) tend to be expensive. Moreover, there are not many substances whose single crystals are easy to prepare. Pressed polycrystalline materials, sometimes containing two or more salts (e.g., a mixture of  $\text{Ag}_2\text{S}$  and  $\text{AgI}$  in an iodide ISE) and possibly also a binder, are most common. Membranes with polycrystalline particles dispersed in a polymeric matrix (such as Pungor's halide electrodes with silver halide precipitates in a silicone rubber matrix) have virtually disappeared now, primarily because they exhibit poorer dynamic properties than the former types.

The other group comprises ISEs with liquid membranes. The classical type (Figure 2C) is no longer used because of technical limitations (imperfect filling of the pores of the diaphragm with the liquid membrane material, leading to short-circuiting of the sample and internal solution, bleeding of the membrane material from the diaphragm). At present, PVC membranes are used, containing the active substance and usually a suitable plasticizer that may play an active role in the ISE response.

In both groups of ISE, the internal standard solution can be replaced by a solid-state contact, e.g., a simple metal contact (solid-state ISEs) (Figures 2D and 2E). This has certain practical advantages, as the electrodes are more robust, can be used in any position (e.g., upside down when analyzing a single drop of a sample solution placed over the ISE membrane), and, in the case of coated-wire ISEs (Figure 2E), are easy to prepare, just by dipping a wire in the membrane solution and allowing the solvent to evaporate. On the other hand, the potential difference between the membrane and the metal is poorly defined and the absolute ISE potentials are often poorly reproducible. These electrodes can readily be used for end-point

**Table 2** Some practically important ISEs

Analyte	Membrane
$\text{H}^+$	Solid, homogeneous, glass
$\text{Cl}^-$	Solid, AgCl precipitate
$\text{Br}^-$	Solid, AgBr/ $\text{Ag}_2\text{S}$ precipitate
$\text{I}^-$	Solid, AgI precipitate
$\text{S}^{2-}$	Solid, $\text{Ag}_2\text{S}$ precipitate
$\text{F}^-$	Solid, homogeneous, $\text{LaF}_3$ single-crystal doped with Eu(II)
$\text{Cd}^{2+}$	Solid, $\text{CdS}/\text{Ag}_2\text{S}$ precipitate

detection in titrations; for direct measurements, it is necessary to calibrate them frequently.

The most common classical ISEs are summarized in Table 2.

## Gas Sensors, Biosensors, and ISFETs

Gas sensors and biosensors are obtained by fixing an auxiliary chemical or biochemical system over the ISE membrane. The analyte reacts with the auxiliary system with production or consumption of the ion that is sensed by the ISE. Two basic types of gas sensor, the Severinghaus electrode and the 'air-gap' electrode, are described elsewhere in this encyclopedia.

Biosensors consist of a common ISE, on the membrane of which an enzyme, a thin layer of tissue containing a suitable enzyme, a culture of

**Figure 3** Schematic diagram of an ISFET: 1, drain; 2, source; 3, substrate; 4, insulator; 5, metal lead; 6, reference electrode; 7, sample solution; 8, ion-selective membrane; and 9, encapsulant. 6, 7 and 8 replace the original metal gate of the FET. (Reprinted with permission from Janata J and Huber RJ (1979) *Ion-selective field effect transistors*. *Ion-selective Electrode Reviews* 1: 31–79; © Elsevier.)

microorganisms, cells, or organelles, is suitably fixed (e.g., in a plastic, porous matrix). Immunobiological systems (antigens or antibodies) can also be used. Examples of such sensors include:

which represents a sensor for L-amino acids, or

which is a urea sensor.

The principle of the ISFET (CHEMFET, CSFET) follows from **Figure 3**. The ion-selective membrane, replacing the metal gate, controls the current between the source and drain, which is measured. The main advantages of ISFETs involve small size and the possibility of placing several selective sensors (membranes) on a single chip. Furthermore, the response is rapid (in milliseconds, compared with classical ISEs whose response amounts to tens of seconds, and gas sensors and biosensors responding within a few minutes) and the impedance is low (compared with classical ISEs whose impedances are usually greater than 1 MΩ). On the other hand, the signal is not sufficiently stable (frequent recalibration measurements are necessary) and technical problems may be involved in producing a selective membrane on the chip surface and encapsulating the chip in a suitable insulator.

## Applications

The application range of ISEs is governed by two major features:

1. the apparatus is cheap and simple; measurements are simple and rapid and
2. the activities of ions, not their overall analytical concentrations, are measured.

Hence, ISEs find use primarily in simple determinations, in which a precision corresponding to a relative standard deviation of a few percent and a typical limit of determination of  $\sim 10^{-5} \text{ mol l}^{-1}$  are satisfactory and the sensor selectivity is sufficiently high, so that no sophisticated separation step is necessary. The above analytical parameters can be improved when ISEs are employed for end-point detection in titrations.

ISEs are often used to advantage for continuous monitoring and are very suitable as detection devices in flow injection analysis. However, they are not particularly convenient for detection in liquid chromatography or capillary electrophoresis, because of rather sluggish response, especially at low analyte concentrations, and a limited sensitivity of measurement.

The fact that the ion activities are measured rather than concentrations is ambivalent from the point of view of practical measurements. It is a great advantage for speciation purposes and for study of acid–base complexation and precipitation equilibria in solution. On the other hand, it is a drawback when the total content of an analyte in a sample is to be found, as great care must be taken to compensate or correct for interactions of the analyte with the sample matrix and the ambient atmosphere during calibration and measurement itself (cf. the problem of complexation of fluoride with iron(III) and aluminum(III) ions in analyses of natural waters, or oxidation of sulfide by atmospheric oxygen).

When an ISE is to be calibrated in terms of activity, conventional activity scales must be employed, which places great demands on the correct selection of the initial assumptions, the accuracy and precision of measurement, and introduces another element of uncertainty to the analytical results.

A large number of ISEs for a variety of analytes has been described in the literature. Only a few of them have found real routine use (**Table 2**). The glass pH ISE is unrivalled; in fact, the overwhelming majority of pH determinations in all fields of human activity is done potentiometrically with the glass electrode. Moreover, the pH ISE is very often used in more complex sensors, such as the Severinghaus-type gas probes and enzyme sensors.

The fluoride ISE is very popular, because it is highly selective and reliable, the determination of

fluoride is very important in water treatment and in environmental protection, and there are not many alternative analytical methods available. Potassium and calcium ISEs are very valuable in clinical analysis, as they determine the free ions in physiological samples, while spectral methods provide the total concentrations of the metals.

The sulfide ISE is sensitive, reliable, and useful especially in analyses of the atmosphere and waters. The nitrate ISE does not exhibit particularly good analytical properties, but it enables very fast and simple orientative determinations of nitrate in, e.g., waters, vegetables, and foodstuffs, which is welcome with regard to public hygiene. ISEs for various inorganic anions have somewhat lost their importance in competition with ion chromatography and those for inorganic cations often cannot compete with spectral methods; nevertheless, ISEs for copper(II), lead(II), and cadmium(II) ions are sometimes useful for end-point detection in complexometric titrations.

There are many biosensors based on ISEs, e.g., for urea, amino acids, and a wide range of biologically important substances, but they are mostly useful in highly specialized determinations. Ion-selective FETs and similar sensors should be very useful owing to their general advantages (see the previous section), but their wider routine use has so far been hampered by their drawbacks, which are rather poor signal stability and technical problems with the chip insulation. In competition with voltammetric sensors, ISFETs often lose because of their smaller versatility. On the other hand, the Severinghaus-type gas sensors have been practically very useful, especially in monitoring environmentally important gases, e.g., sulfur and nitrogen oxides, ammonia, and other gases.

## Introduction

Glass electrodes sensitive to hydrogen ions are the most commonly used sensors in chemistry and related disciplines. They belong to the group of potentiometric

membrane sensors and are constructed in various configurations, depending on the application. Their basic design and properties are described and discussed in this article. Among their important properties is the selectivity, which depends on the composition of the glass. Glass electrodes are used mainly for pH measurements, but they may compose a part of more sophisticated systems in gas sensors or enzymatic sensors. Recently glasses based on a nonsilica structure have been used in potentiometric measurements.

## Origin of Glass Electrodes

Glass electrodes are ion-selective electrodes that belong to the group of electrodes with a noncrystalline solid membrane. Typical glasses are supercooled liquids with a network composed most commonly of silicon oxide; however other compositions may have similar properties and can be used as sensors.

The formation of an electric potential difference on a thin glass membrane in contact with solutions was observed by Cramer in 1906 and used for construction of a device for measuring the acidity of solutions by Haber and Klemensiewicz in 1909. Due to the high resistance of the glass membrane, practical application in routine measurement of acidity, and of course solution pH, was postponed until the invention of vacuum tube amplifiers, and later semiconductors. One of the first types of glass used in manufacturing electrodes was introduced in 1928–1929 by Corning under the designation 015. The research devoted to the mechanism of this electrode action was a stimulus that helped to develop and introduce other types of ion-selective electrodes.

## Electrode Design

A typical glass electrode (Figure 1) consists of a thin glass membrane (thickness 50–300  $\mu\text{m}$ ) at the end of a glass tube acting as (a) an insulator and (b) as a container of the internal solution in which the

internal (reference) electrode is immersed. This internal electrode is usually a silver/silver chloride electrode, and therefore the internal solution should contain a fixed concentration of chloride ions. Thus the glass electrode is in fact a half-cell with a membrane forming a contact to the other half-cell:

The resistance of the whole electrode, depending on its composition and dimensions, is in a broad range of 1–1000 M $\Omega$ . Due to the high resistance the cable connecting it to the measuring device (voltmeter, pH meter) must be protected from electrostatic interferences. The potential difference between the two sides of the glass membrane is proportional to the difference between the pH values on both sides, according to the Nernst equation

$$\Delta E = 2.303 RT/F(\text{pH}_1 - \text{pH}_2) \quad [1]$$

if the electrode for hydrogen ions is considered. To measure an unknown pH value it is therefore necessary to know the pH on one side of the membrane and measure  $\Delta E$ . In practice, for determination of the unknown pH value there is no need to know the exact pH of the internal solution but only to keep it constant. The cell with glass and reference electrodes is calibrated with buffer solutions used as hydrogen activity standards. The same principle is the basis of measurements with cation-selective electrodes that measure the pM rather than pH.

## Composition of Glass Membranes

A glass membrane is composed of oxides such as  $\text{SiO}_2$ ,  $\text{B}_2\text{O}_3$ ,  $\text{P}_2\text{O}_3$ ,  $\text{As}_2\text{O}_3$ , and  $\text{GeO}_2$  and oxides of monovalent or divalent metals e.g.,  $\text{Na}_2\text{O}$ ,  $\text{K}_2\text{O}$ ,  $\text{Li}_2\text{O}$ ,  $\text{CaO}$ . The most common glass membranes are, however, based on the silicon skeleton, containing oxygen atoms around the silicon tetrahedrons. The oxygen may form bridges between the silicon atoms or be nonbridging. The latter can be associated with single charged cations. The alkali metal cations may be exchanged with ions in solution and generate the potential response of the glass electrode. The analyte ions on the surface sites tend to diffuse inside the hydrated gel layer. Such diffusion probably takes place by means of a defect and jump mechanism in which the interstitial cations play a major role. The tendency to interact more selectively with a given ion depends on the composition of the glass. The typical glass composition for a hydrogen ion-sensitive electrode (Corning 015) contains 22%  $\text{Na}_2\text{O}$ , 6%  $\text{CaO}$ , and 72%  $\text{SiO}_2$  and responds according to the Nernst equation (eqn [1]) up to pH 11–12. Replacement of sodium for lithium

Increased selectivity for	Membrane type	Chemical composition (mol%)
H <sup>+</sup>	Corning 015	22% Na <sub>2</sub> O, 6% CaO, 72% SiO <sub>2</sub>
Na <sup>+</sup>	NAS 11-18	11% Na <sub>2</sub> O, 18% Al <sub>2</sub> O <sub>3</sub> , 71% SiO <sub>2</sub>
K <sup>+</sup>	NAS 27-04	27% Na <sub>2</sub> O, 4% Al <sub>2</sub> O <sub>3</sub> , 69% SiO <sub>2</sub>
Li <sup>+</sup>	LAS 15-25	15% Li <sub>2</sub> O, 25% Al <sub>2</sub> O <sub>3</sub> , 60% SiO <sub>2</sub>
NH <sub>4</sub> <sup>+</sup>	NAS 27-03	27% Na <sub>2</sub> O, 3% Al <sub>2</sub> O <sub>3</sub> , 67% SiO <sub>2</sub> , 3% ZnO

**Figure 2** Schematic representation of the hydrated layer of a pH-sensitive glass membrane electrode. I, internal reference solution; II, external (sample) solution of unknown pH.

extends this range up to pH 13. The partial replacement of silicon dioxide by trivalent element oxides favors the selectivity for alkali metal cations as the excess of negative charge must be neutralized by the alkali metal cations. An appropriate composition of the glass membrane enables us to use them as sensors for several metal cations. The preferred composition of some glasses used in ion sensors is presented in Table 1.

Major changes in the composition of glasses cannot be made arbitrarily because excessive amounts of alkali metal oxides lower the membrane durability in solutions. On the other hand, too high a proportion of silica decreases the hydrophilicity of the membrane, which is indispensable for proper functioning of the membrane. The optimum water uptake by the hydrated layer of the electrode membrane varies from 50 to 100 mg cm<sup>-3</sup>. The thickness of the hydrated layer on both sides of the membrane, which is responsible for the electrode response, varies from 5 to 100 nm (Figure 2). Therefore drying out of the membrane is destructive to the electrode performance. The lifetime of glass electrodes depends on the glass composition, aggressivity of solutions, and temperature. An alkaline solution affects the silicon-oxygen network, and acid attack causes the replacement of metal ions by hydrogen ions, in the hydrated silica layer. Special electrodes can work up to 80°C,

but an increase in temperature promotes solution attack on the membrane and changes the parameters of the electrode. Changes in the temperature influence not only the prelogarithmic term of the Nernst-Nikolsky equation but also the equilibria in the solution and at the phase boundaries. A glass electrode with the internal redox system Pt|I<sub>2</sub>/I<sup>-</sup> replacing the usual silver/silver chloride system is much less dependent on the temperature changes (Ross electrode).

### Selectivity

The Nernstian response, i.e., range of the linear dependence of potential versus pH, in the absence of interfering ions extends usually from pH 1 up to 11; however, many contemporary electrodes, depending on the glass composition, have made possible pH measurements up to pH 13. The response of the glass electrodes to metal cations extends down to 10<sup>-5</sup> mol l<sup>-1</sup>, and this is caused mainly by the presence of interferents (hydrogen ions for cation electrodes).

A glass pH electrode exhibits the so-called alkaline error, which means that in the alkaline pH range the potential response is influenced by the presence of sodium ions. The study of this behavior gave rise to the Nikolsky equation,

$$E = E_0 + \frac{RT}{z_i F} \ln \left( a_i + \sum K_{ij}^{\text{pot}} a_j^{z_i/z_j} \right) \quad [2]$$

which is an expanded form of the Nernst equation valid in cases when apart from the main ion,  $a_i$ , with charge  $z_i$ , other ions,  $a_j$ , with charge  $z_j$ , influence the response. In the case of the sodium ion error  $a_j = a_{\text{Na}}$ . The Nikolsky equation indicates the importance of the electrode selectivity, which is quantitatively expressed by the selectivity coefficient,  $K_{ij}^{\text{pot}}$ . The values of selectivity coefficients are important when characterizing the behavior of electrodes sensitive to metal ions. However, these values are not real constants characteristic for a given type of electrode as they depend on the method of measurement and the history of the electrode. Their limiting values are expressed by the product of the constant for the exchange reaction, e.g.,

and the ratio of the ion mobilities,

$$K_{\text{Na,H}}^{\text{pot}} = K_{\text{exch}} \frac{U_{\text{Na}}}{U_{\text{H}}} \quad [3]$$

The values of the selectivity coefficients for some glass electrodes are given in Table 2.

The response times (95% of the equilibrium potential change) given in the literature often correspond to the response time of the whole cell. They are of the

order of a few seconds but also depend on the glass composition, the presence of interferents, the concentration, the temperature, and the electrode ageing.

The measured potential may also be influenced by the so-called asymmetry potential. This is a residual potential between the two glass membrane surfaces when the solutions on both sides are identical. The asymmetry potential is due to differences in structural stresses at the two surfaces, differences in the surface history (ageing), and interaction with different solutions. The asymmetry potential may change with time.

### Applications

Commercial glass electrodes, mostly for pH measurements, differ in construction because they have to serve different purposes. The electrode tips may have different shapes, including tubular flow-through electrodes (Figure 3). Special electrodes are used under conditions of high pressures or high temperatures or

in shock conditions. Electrodes for medical applications, in particular for measurements *in vivo* and control of biotechnological processes, should not be destroyed during sterilization at 120°C. Special construction is necessary for microelectrodes for biochemical purposes. They can be as small as 0.5  $\mu\text{m}$  in diameter to enable measurements within single cells. In many cases it is convenient to use combination electrodes that contain the indicator glass membrane electrode and the reference electrode in one rigid body (Figure 4A).

Glass membrane electrodes, mainly used for pH measurements but also for the  $\text{NH}_4^+$  ion are used for construction of gas sensors (Figure 4B). Such sensors, based on a principle presented by Severinghaus (1958), consist of glass electrodes covered by a thin film made of porous hydrophobic plastic, so that the solution cannot penetrate into the pores. A thin layer of an electrolyte solution is located between the surface of the film and the glass surface. The pH value of that solution changes under the influence of a gas (e.g.,  $\text{NH}_3$ ,  $\text{CO}_2$ ,  $\text{SO}_2$ ), diffusing through the film and is the measure of the gas concentration in the sample solution.

Another type of multiple membrane sensor consists of a glass electrode in contact with a thin layer of solution, being covered with an immobilized enzyme layer. The enzyme (e.g., urease) catalyzes the

**Table 2** Selectivity coefficients,  $K_{ij}^{\text{pot}}$ , for some glass membrane electrodes

reaction of the analyte (e.g., urea) and the products of the reaction  $\text{CO}(\text{NH}_2)_2 + \text{H}_2\text{O} \rightarrow \text{CO}_2 + 2\text{NH}_3$ . The resulting change in the pH of the solution in contact with the glass electrode allows quantitative determination of the analyte (in this case urea).

## Chalcogenide Glass Electrodes

The general term 'glass electrode' is also used in connection with electrodes whose membrane is composed of glasses of different composition and different construction from conventional glass electrodes. The glass membrane is composed of amorphous solids that are binary, ternary, or multicomponent compounds of the elements of group III, IV, or V (boron, aluminum, gallium, germanium, phosphorus, arsenic, antimony) of the periodic table with sulfur, selenium, or tellurium. They can be both stoichiometric (e.g.,  $\text{As}_2\text{S}_3$ ,  $\text{GeS}_2$ ) and nonstoichiometric (e.g.,  $\text{As}_x\text{Se}_{1-x}$ ). Often the membranes are doped with transition metal compounds. Typical glass membranes are obtained by melting the components and forming the membrane proper from the homogeneous melt. A chalcogenide glass membrane is obtained as a disk cut from the solidified melt, and after polishing is pasted into the plastic body in a way similar to that for crystalline ion-selective electrodes.

The chalcogenide glass electrodes may be selective e.g., for iron(III) (glass containing  $\text{Fe}_n\text{Se}_{60}\text{Ge}_{28}\text{Sb}_{12}$ ), copper(II) ( $\text{Cu}_6\text{As}_4\text{S}_9$  – sinnerite), silver(I), lead(II), and cadmium(II). The way it functions is not yet clear: it may be sensitive to powerful redox systems, its characteristics may be influenced by doping, and its behavior is often non-Nernstian. Such a glass may exhibit a mixed ionic or electronic conductance.

## Introduction

The classification of ion-selective electrodes (ISEs) into glass, solid-state, and liquid electrodes follows historical tradition and it also reflects differences in electrode fabrication procedures. As far as glass and liquid electrodes are concerned, the classification is more or less in agreement with usage of the terms glassy and liquid state in other areas of chemistry. But the term 'solid electrodes' defines a variety of potentiometric sensors. Membrane electrodes from crystalline solid materials belong to this group. These can be single crystals, pellets pressed from crystalline powder, or solidified melts. The crystalline material may be a single compound or a homogeneous mixture of compounds (e.g., AgI and  $\text{Ag}_2\text{S}$ ). If the mechanical

properties of a pressed pellet are unsatisfactory it may be advantageous to embed the crystals into an inert polymer matrix, such as silicone rubber. These are called heterogeneous membranes. Amorphous or glassy solids have also been used as membrane materials in ISEs and with the exception of silicate-type glasses these are usually regarded as solid electrodes.

Semiconductor processing technologies have often been used to produce ISEs, particularly as field-effect transistors (FETs) with ion-selective layers like silicon oxide over the gate region. Such ion-selective FETs (ISFETs) are, in principle, solid ISEs, although sometimes the dielectric over the gate is covered with a second, liquid membrane-type layer to achieve different selectivities.

Polymeric materials may also be used as electrodes. Very thin polymeric films may be produced at the surface of metal electrodes like platinum. Some of these electrodes may also be useful as ion-selective potentiometric sensors.

reaction of the analyte (e.g., urea) and the products of the reaction  $\text{CO}(\text{NH}_2)_2 + \text{H}_2\text{O} \rightarrow \text{CO}_2 + 2\text{NH}_3$ . The resulting change in the pH of the solution in contact with the glass electrode allows quantitative determination of the analyte (in this case urea).

## Chalcogenide Glass Electrodes

The general term 'glass electrode' is also used in connection with electrodes whose membrane is composed of glasses of different composition and different construction from conventional glass electrodes. The glass membrane is composed of amorphous solids that are binary, ternary, or multicomponent compounds of the elements of group III, IV, or V (boron, aluminum, gallium, germanium, phosphorus, arsenic, antimony) of the periodic table with sulfur, selenium, or tellurium. They can be both stoichiometric (e.g.,  $\text{As}_2\text{S}_3$ ,  $\text{GeS}_2$ ) and nonstoichiometric (e.g.,  $\text{As}_x\text{Se}_{1-x}$ ). Often the membranes are doped with transition metal compounds. Typical glass membranes are obtained by melting the components and forming the membrane proper from the homogeneous melt. A chalcogenide glass membrane is obtained as a disk cut from the solidified melt, and after polishing is pasted into the plastic body in a way similar to that for crystalline ion-selective electrodes.

The chalcogenide glass electrodes may be selective e.g., for iron(III) (glass containing  $\text{Fe}_n\text{Se}_{60}\text{Ge}_{28}\text{Sb}_{12}$ ), copper(II) ( $\text{Cu}_6\text{As}_4\text{S}_9$  – sinnerite), silver(I), lead(II), and cadmium(II). The way it functions is not yet clear: it may be sensitive to powerful redox systems, its characteristics may be influenced by doping, and its behavior is often non-Nernstian. Such a glass may exhibit a mixed ionic or electronic conductance.

## Solid-State

## Introduction

The classification of ion-selective electrodes (ISEs) into glass, solid-state, and liquid electrodes follows historical tradition and it also reflects differences in electrode fabrication procedures. As far as glass and liquid electrodes are concerned, the classification is more or less in agreement with usage of the terms glassy and liquid state in other areas of chemistry. But the term 'solid electrodes' defines a variety of potentiometric sensors. Membrane electrodes from crystalline solid materials belong to this group. These can be single crystals, pellets pressed from crystalline powder, or solidified melts. The crystalline material may be a single compound or a homogeneous mixture of compounds (e.g., AgI and  $\text{Ag}_2\text{S}$ ). If the mechanical

properties of a pressed pellet are unsatisfactory it may be advantageous to embed the crystals into an inert polymer matrix, such as silicone rubber. These are called heterogeneous membranes. Amorphous or glassy solids have also been used as membrane materials in ISEs and with the exception of silicate-type glasses these are usually regarded as solid electrodes.

Semiconductor processing technologies have often been used to produce ISEs, particularly as field-effect transistors (FETs) with ion-selective layers like silicon oxide over the gate region. Such ion-selective FETs (ISFETs) are, in principle, solid ISEs, although sometimes the dielectric over the gate is covered with a second, liquid membrane-type layer to achieve different selectivities.

Polymeric materials may also be used as electrodes. Very thin polymeric films may be produced at the surface of metal electrodes like platinum. Some of these electrodes may also be useful as ion-selective potentiometric sensors.

Thin layers of solids like chalcogenides may also be deposited on a metal surface by electrolysis or by vacuum deposition techniques. These electrodes are closer to solid ISEs than to traditional electrodes of the second kind.

This article focuses on self-supporting disk-type membranes with liquid or solid internal contact, which is the typical configuration of most commercial ISEs. Other solid ISEs are briefly discussed.

All-solid-state electrodes refer to where there are no free-flowing liquids used in the electrode construction. The practical advantages that result include insensitivity to electrode orientation and smaller size. The difficulty with this structure is often the instability of the potential developing at the back contact of the ISE membrane. Sometimes such an ISE is called all-solid-state even if the sensitive membrane is a liquid membrane.

## History

Glass electrodes have been available since the early 1900s and solid-state electrodes are even older. The first membrane-type solid electrodes were made in the 1930s without arousing much interest. The potential of these devices was realized only when a variety of good and sufficiently selective electrodes were developed by Pungor and co-workers and subsequently by Frant and Ross. The former group embedded crystal-line precipitates in a silicone rubber matrix whilst Frant and Ross made single crystal fluoride electrodes and pressed pellet electrodes for some other ions. Both groups succeeded in transferring their inventions into industrial production. Since then many workers have contributed to the analytical utilization and understanding of the operation of solid ISEs. The work on ISFETs was initiated by Bergveld.

## Principles

Ion-selective electrode theories need to explain why a stable electromotive force (e.m.f.) develops in the measurement cell, how the concentration of the primary ion and interfering ions affect the e.m.f., and how fast the e.m.f. responds to changes in sample composition. The theories are usually based on a model description of the measurement cell and the process occurring in it. Before going into details it should be noted that different, sometimes mutually contradicting models, may equally well explain the same potentiometric observation. In fact, different real systems may behave potentiometrically in the same way. In other words, potentiometric observations are usually not very useful as positive proof of a model; additional information, e.g., from surface spectroscopies, impedance measurements, radiotracer studies, is necessary.

In the following discussion an electrode membrane consisting of a sparingly soluble salt  $I^+A^-$  and separating the aqueous sample from the inner reference solution is considered. Suitable reference electrodes immersed in the two solutions complete the cell used for e.m.f. measurement.

### The Nernst Equation

The relationship between an e.m.f. ( $E$ ) and primary ion activity is ideally given by the Nernst equation:

$$E = E^\circ + \frac{RT}{F} \ln a_1 \quad [1]$$

where  $E^\circ$  (standard e.m.f.) is a constant,  $R$ ,  $T$ , and  $F$  have their usual meaning, and  $a_1$  is the activity of the primary ion  $I^+$  in the sample. This equation may be derived by observing that the e.m.f. adds up from several potential drops in the cell but sample composition should influence only the potential drop across the membrane and at the sample/reference electrode liquid junction (in cells with transference). Neglecting the changes of the latter we need to pay attention only to the potential drop between sample and internal reference solution, i.e., across the membrane. In the absence of interferences this potential difference can be calculated from thermodynamic considerations:

$$\Delta\phi_{1,2} = \frac{RT}{F} \ln \frac{a_{1,1}}{a_{1,2}} = \frac{RT}{F} \ln \frac{a_{A,2}}{a_{A,1}} \quad [2]$$

where  $a_{1,1}$  is the activity of the primary cation in the sample,  $a_{1,2}$  is the same in the internal reference solution, and the  $a_{A,s}$  are the respective quantities for the primary anion. The composition of the internal reference solution is usually independent of the sample, so that eqn [1] or a similar equation for the primary ion is valid.

When writing eqn [2] it has been assumed that the internal reference solution is a soluble salt of  $I^+$  when this ion is measured, and a soluble salt of  $A^-$  when this is the analyte. In practice, there is no need to change the internal electrolyte according to the measured ion. If the internal solution is an  $I^+$  salt but the analyte is an  $A^-$  salt the Nernst equation is still valid albeit with a different  $E^\circ$ . **Figure 1** shows typical calibration lines with an unchanged internal solution. Apparent deviations from the Nernstian straight line are observed at low analyte concentration due to membrane solubility (see the section on detection limit).

The  $I^+A^-$  membrane may be contacted on the inner side with a solid, electronically conducting material to form an all-solid-state electrode. This is generally regarded to be a sound practice only if the two contacting solid phases can equilibrate, i.e., there is at least one charged species (ion or electron)

**Figure 1** Typical calibration lines of a silver halide, AgX electrode for  $\text{Ag}^+$  and  $\text{X}^-$ .

that can easily transgress the phase boundary in both directions. One example is metallic silver (or silver containing adhesive) in contact with a silver salt membrane. Thermodynamic reasoning yields in this case again the Nernst equation. Solid contacts that do not appear to fulfill the above requirement have occasionally been used successfully.

### Detection Limits

The analytically useful concentration range of a particular electrode type may be limited both from the higher and the lower ends. At the high end the membrane material may rapidly deteriorate, e.g., due to dissolution in complex form, e.g., AgCl-based chloride electrodes in concentrated chloride solutions, or AgI-based cyanide electrodes in strong cyanide solutions. The lower detection limit is more crucial for practical applications, and typically is governed by the solubility of the membrane material. This statement is quite natural if the sample becomes saturated with the membrane material during the time of measurement. In most practical cases the sample volume is large, the membrane solubility is low, so that the rate of equilibration is rather slow, because it is determined by the rate of membrane dissolution. One can assume, however, that at the membrane/solution interface local equilibrium exists, so that the concentration detected by the electrode in a zero concentration solution is indeed the saturation concentration. Near the detection limit the calibration line will be curved; useful equations have been derived to describe this range. The lower detection limit can be extended, however, either by applying a small current to the electrode, or by using hydrodynamic flow (rotating disk electrode or continuous flow analysis). The first method removes dissolved ions from the electrode surface, the second one diminishes the diffusion layer at the electrode surface,

thereby enhancing the flux of dissolved ions into the bulk solution.

Sometimes the practical detection limit is well above the solubility value. This may be due to interferences, secondary equilibria, and/or the small exchange current density at the interface.

### Interferences

Different types of interferences may be encountered in practice; some important ones will be mentioned here. Corrosive media may destroy the membrane or the electrode housing.

Ions with the same charge sign as the analyte may be sensed by the electrode. In this case, the Nicolsky equation is often approximately valid:

$$E = E^\circ + \frac{RT}{z_1 F} \ln(a_1 + K_{IJ}^{\text{pot}} a_J^{z_1/z_I}) \quad [3]$$

where  $a_J$  is the activity of the interfering ion,  $z_I$  and  $z_J$  are the respective charges of ions I and J, and  $K_{IJ}$  is the selectivity coefficient. As a simple case one can consider a membrane of  $\text{I}^+ \text{A}^-$  and an interfering ion  $\text{J}^+$ , which forms a more soluble precipitate  $\text{J}^+ \text{A}^-$  than  $\text{I}^+ \text{A}^-$ . If the electrode is in solubility equilibrium with a solution of  $\text{I}^+$  and subsequently more and more  $\text{J}^+$  is added to the solution, no precipitate  $\text{J}^+ \text{A}^-$  should form until

$$a_J \leq \frac{L_{JA}}{L_{IA}} \cdot a_I \quad [4]$$

(at least close to the electrode surface), where the  $L$ s are the respective solubility products of the precipitates. Above this limit  $\text{J}^+ \text{A}^-$  can be formed at the electrode surface or the surface is converted into a mixed crystal  $\text{IJA}_2$ . Exact theoretical treatment of these processes is not always possible. Yet for some cases it can be derived and in many cases it can be found experimentally that the selectivity coefficient is approximately  $L_{IA}/L_{JA}$ .

The interference may also be caused by agents forming a soluble complex with either component of the membrane salt and/or with the analyte. A prime example is the effect of  $\text{CN}^-$  on AgI electrodes.  $\text{CN}^-$  corrodes the AgI membrane by the reaction:

The cell voltage measured in a solution of  $\text{CN}^-$  (with or without the presence of  $\text{I}^-$ ) is determined by the stationary iodide concentration at the membrane/solution interface. This concentration in turn is determined by the rate of dissolution of AgI and the rate of  $\text{I}^-$  transport from the electrode surface to the solution bulk. Thus, the cell voltage (which is not an

e.m.f. because there is no equilibrium) depends on rate processes. Nevertheless, calculations show that the Nicolsky equation is approximately valid for the  $\text{CN}^-$  interference at the AgI electrode, with a selectivity coefficient of 0.5.

### Response Time

The time response of solid ISEs to sudden concentration changes of the primary ion is usually very fast, less than 100 ms for 90% of the total e.m.f. change, except in the vicinity of the detection limit. Such values can be observed, however, only in equipment of special design. In practical cells the time course of concentration change at the electrode surface usually cannot be made sufficiently abrupt and the measured time response is slower than that of the ISE. Many valuable results have been obtained with suitable equipment and approximate equations were given to describe the time course of response.

### Potential Stability and Lifetime

The short time repeatability of the e.m.f. measurement with solid ISEs is usually good, typically within 0.1 mV. The long-term potential stability in the same solution is an important parameter in monitoring applications. Literature data appear to be scarce in this respect. A value of 1 mV per week can be regarded as satisfactory.

## Practical Electrodes of Conventional Design

### Electrode Construction and Compensation of Temperature Effects

In commercial electrodes, the solid membrane is pressed or glued into a plastic electrode shaft. The internal contact is either solid, typically silver, or an internal filling solution is used with a silver-silver chloride reference element dipping into this electrolyte (Figure 2). The type and composition of the internal contact is important for the temperature dependence of the e.m.f. In laboratory work temperature compensation is rarely required, but in industrial or environmental monitoring it is necessary. The best practice is to use a variable internal filling solution and adjust its composition to the expected analyte concentration range. The external and internal reference elements should also be as similar as possible. In this way a nearly symmetrical cell is obtained with close to zero e.m.f. in the monitored concentration range. Under such conditions temperature effects are small and correction should be easier (provided that there are no temperature gradients within the measurement cell).

**Figure 2** Solid electrodes with (A) solid and (B) liquid internal contacts.

### Lanthanum(III) Fluoride Electrodes

Until very recently successful  $\text{LaF}_3$  electrodes could only be made from lanthanum(III) fluoride ( $\text{LaF}_3$ ) single crystals. The hexagonal lattice of this crystal consists of layers of  $\text{LaF}_2^+$  with a fluoride layer on either side. The fluoride ions have appreciable mobility in the lattice, which results in a specific conductivity of  $\sim 3 \times 10^{-7} \text{ S cm}^{-1}$ . This value can be raised 10-fold by doping with 1%  $\text{EuF}_3$ . The electrode response is linear from about  $10^{-6}$  to  $1 \text{ mol l}^{-1} \text{ F}^-$ , the detection limit is  $\sim 10^{-7} \text{ mol l}^{-1}$ . These data are valid for nearly neutral pH values; at higher pH  $\text{OH}^-$  ions interfere and at low pH values HF and  $\text{HF}_2^-$  begin to form. Apart from this, interferences are scarce and caused by the complexation of the analyte (fluoride) with metal ions such as iron(III) and aluminum(III) in the sample. The interferences can mostly be avoided by using a suitable sample adjustment buffer solution (total ionic strength adjustment buffer). The response time of the electrode is fast except near the detection limit.

The fluoride ISE has been the most successful of all ISEs. This is so partly because it has uniquely good characteristics including a long service lifetime and partly because the potentiometric fluoride determination is so much more convenient than any

alternative method. The applications extend from analysis of minerals and teeth to other biomedical, environmental, and industrial determinations.

### Silver Sulfide Electrodes

Silver sulfide is an excellent material for a solid-state electrode. It has very low solubility and consequently there are only few potentiometric interferences ( $\text{CN}^-$ ,  $\text{Hg}^{2+}$ ). It can be easily compressed into mechanically stable pellets and it is also accessible as single crystal for electrodes. At ambient conditions (below  $176^\circ\text{C}$ ) its monoclinic  $\beta$ -modification, acanthite, is stable, and shows high ionic conductivity due to silver ions. Silver sulfide electrodes respond to both silver and sulfide ions with good practical detection limits ( $10^{-8}$ – $10^{-7} \text{ mol l}^{-1}$ ) in Nernstian manner. Sulfide analysis is performed in strongly alkaline solutions.

Important applications of this electrode are the direct determination of sulfide (or other sulfur-containing species converted to sulfide) in aqueous solutions and as an indicator electrode in argentometric titrations.

### Silver Halides for Electrodes

The first ISEs were made from silver halide melt or from precipitate with inert silicone rubber binding material. This construction has been replaced in modern commercial electrodes by mixtures of silver halides with silver sulfide. The pure silver halides are difficult to compress into mechanically stable pellets, and this problem is overcome by the silver sulfide admixture. The conductivity is also considerably increased and light sensitivity diminished. The mixture is usually obtained by coprecipitation. In the compressed pellet the presence of some  $\text{Ag}_3\text{SBr}$  and  $\text{Ag}_2\text{SI}$  has been claimed. The detection limits for the halide ions and silver is close to the solubilities ( $10^{-5}$ ,  $10^{-6}$ , and  $10^{-8} \text{ mol l}^{-1}$  for  $\text{AgCl}$ ,  $\text{AgBr}$ , and  $\text{AgI}$ , respectively). For the analysis of chloride below this limit  $\text{Hg}_2\text{Cl}_2/\text{Ag}_2\text{S}$  electrodes have been useful. Important interferences in halide assays are from the less soluble halides, sulfide, cyanide, and thiocyanate. The slow corrosion process of  $\text{AgI}$  in dilute cyanide solutions is the basis for the potentiometric assay of this ion with an iodide selective electrode in alkaline solutions. For the measurement of silver ion the  $\text{Ag}_2\text{S}$  electrode is preferred to the halides. The greatest practical utility among the halide electrodes has been attained by the chloride ISE due to the general importance of chloride assay in analytical chemistry.

### Chalcogenides of Doubly Charged Metal Ions

The most important of this group are copper, lead, and cadmium compounds. With the exception of some nonstoichiometric copper chalcogenides, these

materials are insulators or semiconductors and not suitable for ISE preparation. Coprecipitation with silver sulfide has led, however, to useful electrode materials either as pressed (sintered) pellets or dispersed in an inert binder. The materials are sensitive to the precipitation procedure applied and to the temperature and pressure during compression when pellets are formed. The resulting materials are intimate mixtures or solid solutions of  $\text{PbS}$  or  $\text{CdS}$  with  $\text{Ag}_2\text{S}$ , but in the case of the copper preparation a ternary compound  $\text{Ag}_{1.5}\text{Cu}_{0.5}\text{S}$  (jalpaite) is also formed. Chalcogenide ISEs can be prepared by electrochemical deposition, also with optimized composition, and these electrodes are reproducible and have better performance in flow systems.

The lead electrode is sensitive to surface oxidation and requires periodical repolishing. The linear response for the primary cation usually extends from  $10^{-1}$  to  $10^{-6} \text{ mol l}^{-1}$ ; the detection limit is  $\sim 10^{-7} \text{ mol l}^{-1}$ . These statements hold only in the optimal pH range of  $\sim 4$ – $7$ . At higher pH values the formation of the hydroxides of the divalent metals reduces the upper limit of quantitation. At lower pH the solubility of the sulfides increases and this raises the lower detection limit. The selectivities over alkali and alkaline earth metal ions are very good.

Mercury(II) and silver(I) strongly interfere in every case and copper(II) is an important interferent in sensing lead and cadmium. Copper and lead assays are much more disturbed by the presence of iron(III) than the cadmium assay. A large excess of anions like chloride may interfere with cadmium and lead quantitation but the most notable problem with chloride is found with the copper ISE. The response of these ISEs to complexing agents and complexes of their divalent metal components has been thoroughly studied. The electrode response in the presence of complexes does not always coincide with thermodynamic expectation.

The copper ISE is important for complexation studies in environmental samples. Potentiometric lead and cadmium electrodes are less popular but the lead electrode has been quite useful for indirect sulfate measurements. The electrodes require frequent recalibration.

## Ion-Selective Field-Effect Transistors

Ion-selective electrodes are mostly used in conjunction with a high impedance voltmeter. This means practically that the e.m.f. is measured by charging the gate capacitor of a FET to the cell voltage. The field in the capacitor regulates the source–drain current of the FET, which is measured as the output

**Figure 3** Schematic representation of an ISFET. S, source; D, drain; G, gate; R, reference electrode.

signal. Ion-selective field-effect transistors (ISFETs) are specially designed FETs where the gate material is the ion-selective membrane (Figure 3). For example, the gate can be an oxide insulator, like silicon oxide, which behaves as a pH-sensitive electrode membrane. The proton buffer capacity of this oxide layer will determine the sensitivity of the device. Advantages of ISFETs include the small size, the possibility of mass production, the possibility of integration of sensor and electronics, etc. Their disadvantage is that practical devices usually drift much more than similar electrodes in conventional design. This is a practical problem that can be overcome by compensating for the predetermined drift by a programmed amplifier. Another way to get around the drift problem is to carry out dynamic measurements, e.g., titration of weak acids or bases by integrating the ISFET with a pH actuator (a noble metal electrode that generates protons or hydroxyl ions coulometrically).

## Miscellaneous Designs

Metal chalcogenide solid ISE membranes have been made from single crystals and microcrystalline materials. Several researchers have found that chalcogenide glasses can also be used as ISEs. The characteristics of these materials may surpass those of crystalline materials with respect to chemical stability, selectivity, and sensitivity to redox agents. Sensor arrays of chalcogenide glass electrodes can be constructed by pulsed laser deposition. Artificial neural networks are used for signal processing to detect different heavy metal ions from environmental water samples.

Salts of certain organic radical ions have been found to be suitable for the preparation of solid ISEs, but they appear to have been little used in practice.

Ceramics, like NASICON (sodium super ionic conductor) prepared by the sol-gel method, were found to give selective potentiometric response toward various cations. Selectivity is provided by the

size of the channels, which conduct in the ceramic framework.

Liquid crystals representing an intermediate state between the liquid and crystalline states can also be used to prepare ISEs. A liquid-crystal-type ionophore is dissolved in a liquid crystal solvent to obtain a cation-selective electrode, the selectivity of which is highly temperature dependent.

In recent years, the modification of electrode surfaces has been intensively studied by electrochemists. The trend of surface modification has already reached the ISE field.

Inorganic films, like transition metal hexacyanoferrates, can be chemically or electrochemically deposited onto a conductive surface, and used as ISEs, e.g.,  $K^+$ ,  $Tl^+$ ,  $Cs^+$ ,  $NH_4^+$ , and  $Rb^+$  ions.

Another class of inorganic materials used in the preparation of modified electrodes are zeolite type ion-exchangers possessing shape, size, and charge selectivity. The zeolite is embedded into a polymer matrix and deposited onto a metal surface.

Sol-gel derived glasses, encapsulating neutral carriers were prepared as ion-sensing membranes in ISFETs or as supported membranes in macroelectrodes. Thromobogenicity of the membranes proved to be much better than that of plasticized poly(vinyl chloride) membranes, which makes them successful candidates in the analysis of biological samples.

Successful attempts were made to deposit a molecularly imprinted layer of  $TiO_2$  on the gate of an ISFET by the sol-gel technique. Binding of the analyte to the imprinted inorganic network changed its charge, which in turn controlled the gate potential, giving selective potentiometric response, e.g., to chloroaromatic acids.

Conducting polymers, e.g., polypyrrole, polythiophene, and polyaniline, deposited on electrode surfaces have both ion-exchange and redox properties. In most cases the ionic response is poorly selective, but by carefully choosing the polymerization conditions they can show appreciable selectivity. This is attributed to the micropores formed in the polymer having size and charge complementary to the ion to be measured. Selectivity of the conducting polymers can be greatly enhanced by incorporating ionophores. Conducting polymers can be either electropolymerized or solvent cast onto a substrate like a glassy carbon electrode resulting in an all-solid-state sensor.

The use of methacrylic-acrylic copolymers as a plasticizer-free matrix into which ionophores can be incorporated may speed up the development of miniaturized solid-state ion-sensors. These polymer films can be readily prepared by photocuring, have excellent adhesion properties, and satisfactory long-term stability.

**Table 1** Properties and selected applications of solid ISEs<sup>a</sup>

Electrode type	Concentration range <sup>b</sup> (mol l <sup>-1</sup> )	Approximate slope (mV per decade)	Interferences <sup>c</sup>	Selected applications

<sup>a</sup> The electrode properties given here have been extracted from several manufacturers' literature. Similar, more detailed tables can be found in the references by Cammann and van der Linden.

<sup>b</sup> The sources usually do not specify linear range and detection limit; only a useful concentration range is given.

<sup>c</sup> Only the strongest interferants are given here. These must be absent or present at a much lower concentration than the analyte.

## Applications

Table 1 shows some data for commercially available electrodes and a selection of interesting analytical uses of solid ISEs. The majority of applications has been the determination of fluoride in many kinds of samples. Chloride determinations are next in order of importance. The precision of direct determinations is usually limited to 1–10% rsd. The ruggedness of solid ISEs makes them suitable for online monitoring applications. If monitoring is based on direct measurement frequent recalibrations may be necessary and the temperature compensation may not always be straightforward. Monitors can also be based on titration reactions; in this case less problem may be encountered but more sophisticated hardware will be necessary. Solid ISEs can also be used in different solvents. This may be useful, e.g., in precipitation titrations.

## Liquid Membrane

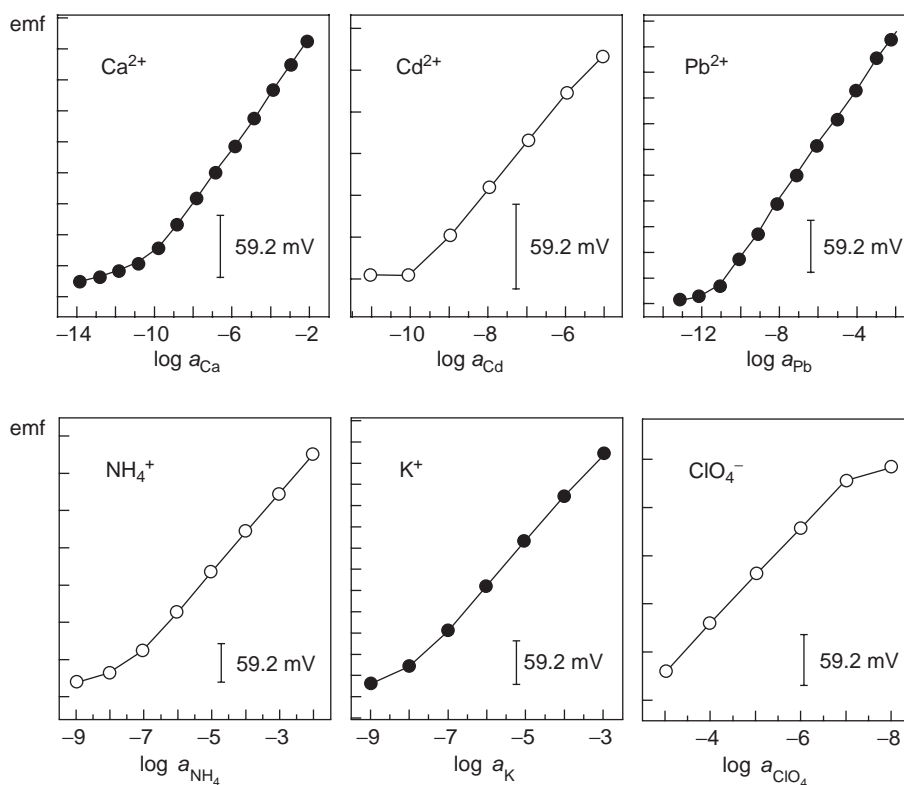

**E Bakker**, Auburn University, Auburn, AL, USA

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Liquid membrane electrodes are a very versatile group of ion-selective electrodes (ISEs) because their response can be rationalized on the basis of liquid-liquid partitioning and complexation principles. Today, liquid membrane ISEs are key components of clinical analyzers in nearly every hospital in the world, with billions of assays performed each year. Their application is steadily broadening with the advent of more selective membrane materials, advances in miniaturization, and the availability of more rugged sensor materials. Recently, numerous liquid membrane electrodes with extremely low detection limits have become available (see **Figure 1**), opening up very important new avenues for this class of sensors. The ion-selective membrane was historically composed of a simple organic liquid, but today either plasticized hydrophobic polymers or plasticizer-free

polymers with low glass transition temperatures are used because of their improved ruggedness. The ion-selective membrane is doped with a number of active ingredients that are either freely dissolved or covalently anchored onto the polymer to avoid leaching. These membrane components are the key ingredients of such sensors: they mediate the selective extraction of the analyte and also make sure that the ISE membrane exhibits ion-exchanger properties. So far, ISEs for more than 60 different analytes have been described. ISEs for polyionic analytes such as heparin, protamine, and DNA have also been developed, demonstrating that they form a truly versatile class of sensors. Fabrication of polymeric ISE membranes is normally done by solvent casting from an organic solution, and can be accomplished with relative ease. The membranes are then either mechanically mounted into an electrode body or glued onto a polymer tubing. The fabrication of microelectrodes is also well established, and numerous microfabrication processes for liquid membrane ISEs have been reported. In traditional setups, an aqueous inner electrolyte solution is placed at the backside of the membrane, but the so-called solid-contact ISEs are

**Figure 1** Response functions of recently described liquid membrane electrodes with very low detection limits in unbuffered samples (Adapted from Bakker E and Pretsch E (2002) The new wave of ion-selective electrodes. *Analytical Chemistry* 74: 420A).

also used, although they may suffer from potential drifts. Two principal classes of liquid membrane ISEs can generally be distinguished: the first contains an ion-exchanger without any molecular receptor properties; the second is based on highly selective ionophores. Modern chemical research mainly deals with the improvement of the second class but numerous commercial ISEs are often still based on the first.

Recommended reviews on this topic are given in Further Reading, and include the biannual reviews in *Analytical Chemistry* on electrochemical sensors, a series of three comprehensive reviews on ionophore-based electrodes, a review on low detection limit ISEs, and recommendations for reporting selectivities including recent listings of ISE selectivities.

### **Ion-Exchanger-Based ISEs**

Liquid or solvent polymeric membranes for ISEs must exhibit ion-exchanger properties. It is known that the concentration of analyte in the membrane phase must remain approximately constant as the sample concentration is changed for a Nernstian response slope to be observed. This can be achieved by doping the liquid membrane with a lipophilic ion-exchanger, for example, tridodecylmethylammonium chloride for anion-selective electrodes or potassium tetrakis(4-chlorophenyl)borate for cation-selective electrodes. Numerous other ion-exchangers have been reported, but their main function is always the same. Before initial use, the liquid membrane is normally conditioned in a solution containing a high concentration of the cation or anion to be measured. During this conditioning period, the hydrophilic counterion of the ion-exchanger in the membrane is replaced with the analyte ion of interest. Because no chemical recognition/complexation takes place, the selectivity of such ISEs is a function of the free energy of solvation of the measured ions in both phases. For anion-selective ISEs (containing an anion-exchanger salt), the observed selectivity sequence always follows the so-called Hofmeister sequence:

where  $\text{R}^-$  is an organic anion. The corresponding selectivity sequence for ion-selective membranes incorporating a cation-exchanger is

Such ion-exchanger-based ISEs have been mainly used for the detection of lipophilic ions such as perchlorate and nitrate, as well as certain electrically

charged drugs and lipophilic quaternary ammonium ions. Note that the thermodynamic selectivity sequences listed above are not always observed in practice. If a strongly interfering but dilute ion is present in the sample (typically at less than  $10^{-4} \text{ mol l}^{-1}$  levels), it does not alter the cell potential significantly. Indeed, low concentrations of these ions are rapidly depleted at the membrane surface and can only insufficiently displace the analyte of interest from the membrane. For only short exposure times, the electrode can often still reliably be used to assess the analyte. Of course, prolonged exposure to samples containing such lipophilic interferents will eventually alter the response characteristics of such ISEs. These characteristics have often been used for sensing applications in samples for which no thermodynamic selectivity was available. This explains why some manufacturers offer ion-exchanger-based ISEs for a variety of ions, even though the basic membrane composition is essentially identical. Clearly, it is much more advisable to use ISEs with better ion-exchange selectivities, which may be achieved with membranes containing suitable ionophores.

### **Ionophore-Based ISEs**

Lipophilic ionophores are essential to achieving a high sensing selectivity with liquid membrane ISEs. As explained above, ion-exchanger-based membranes always show the same selectivity pattern that follows the solvation energies of the ions, but ionophore-based membranes may show very different selectivities. This is achieved by the formation of strong complexes between the extracted analyte ion and the ionophore in the membrane. Complex formation constants have been recently determined in the membrane phase in the range of  $\sim 10^8$  for monovalent to  $\sim 10^{25}$  for divalent ions. With ionophore-based ISEs, the selectivity is now dictated by the free energy of transfer of the ions from the aqueous to the membrane phase, the complex formation constants between the extracted ions and the ionophore, and the concentrations of the active membrane components in the membrane. Because solvation energies are still an important component to the overall selectivity since an ion extraction process is involved, it is normally more difficult to design ISEs for hydrophilic ions than it is for hydrophobic ones. On the other hand, it is often a challenge to design selective receptors for large, bulky ions. Consequently, ionophore-based ISEs for potassium and calcium have been realized early on, while selective sensors for magnesium, lithium, sodium, chloride, and phosphate have only been developed recently or

are still topics of current research. Ionophore-based ISEs for bulky anions such as perchlorate are essentially unknown, but note that ion-exchanger-based ISEs possess a good intrinsic selectivity for such anions (see above).

Figures 2 and 3 show a limited selection of successful ionophores used in liquid membrane ISEs. A much exhaustive list of ionophores has been published in the recent literature. Table 1 summarizes typical membrane compositions of the corresponding ISEs and lists the observed selectivity coefficients. Recall that a small selectivity coefficient indicates a high membrane selectivity: for an interfering ion possessing the same charge as the so-called primary ion, the selectivity coefficient is a weighting factor for the interfering ion activity. In ideal cases, a selectivity

coefficient of  $10^{-4}$ , for example, indicates that a 10 000-fold excess of interfering ion will give the same signal as the primary ion. The relationship is more complicated for ions of different charge or close to the detection limit of the ISE. As shown in Table 1, membrane selectivities may be very high, and explain why such ISEs have been very successful in a number of important applications. Ionophores can be developed on the basis of a variety of recognition principles: bis-crown ionophores, crowns with bulky side groups to prohibit intermolecular sandwich formation, noncyclic amide and thioamide ionophores, basket-shaped calix[4]arene and calix[6]arene ionophores, calixarenes with crown bridges, thiocarbamates, lipophilic bases as  $H^+$ -ionophores, guanidinium derivatives, multitopic

**Figure 2** A selection of cation-selective ionophores used in liquid membrane ISEs (Adapted from Bühlmann P, Pretsch E, and Bakker E (1998) *Chemical Reviews* 98: 1593).

hydrogen bond forming ionophores, metalloporphyrins, corrins, and phthalocyanines with different metal centers and a variety of axial ligands, and aromatic trifluoroacetyl derivatives for the recognition of hydrophilic nucleophiles have been utilized in liquid membrane ISEs. Some of these ionophores are electrically charged in their uncomplexed form, but most are the so-called neutral ionophores.

Ionophores used successfully in ISEs normally share a number of important characteristics. They are highly lipophilic, that is, they are strongly retained in the hydrophobic membrane phase to ensure a long lifetime of the sensor. This is most often achieved by adding long alkyl chains, cyclohexyl, or adamantyl substituents to the structure. They possess a polar moiety or a set of polar functional groups responsible for ion recognition. The rest of the molecule contains hydrophobic regions that are

compatible with the surrounding membrane solvent. The historical argument that ionophore molecules must also exhibit a high mobility has been largely disproved by the availability of a number of membrane materials where the ionophore is covalently anchored onto the polymeric backbone. The covalent anchoring still retains certain ion mobility in the membrane that appears to be sufficient for ISE applications.

The membrane selectivity is not only a function of the ionophore. Membranes of relatively high polarity (such as poly(vinyl chloride) overplasticized with *o*-nitrophenylether) have historically been preferred for the development of divalent-ion-selective electrodes and many anion-selective electrodes. Nonpolar membranes, such as poly(vinyl chloride) overplasticized with bis(2-ethylhexyl)sebacate, are generally more suited for monovalent cations. Note, however, that

the role of membrane polarity on the membrane selectivity has been overrated in the past as there appears to be no direct correlation when a large number of plasticizers are compared. Clearly, other parameters appear to influence selectivity as well, including the tendency to form ion pairs, the availability of functional groups on the plasticizer that can compete with the ionophore, and indirect variations of complex stoichiometries of the ionophore in different solvent environments. For these reasons, the optimization of ISE selectivity is, therefore, to a large part still an empirical science. On the other hand, if the complex stoichiometries are known, optimum membrane concentrations of ionophore and lipophilic ion-exchanger can be predicted. For example, Table 2 lists optimum concentration ratios of ionophore to ion-exchanger for a select number of assumed complex stoichiometries and charges of the two compared ions. Since some ionophores may be capable of forming mixed complex stoichiometries,

these values are best viewed as first guesses to guide the experimentalist.

## Low Detection Limits

Recent research has focused on improving the detection limit of liquid membrane ISEs in samples containing a low total concentration of analyte ion (low detection limits in samples containing a metal ion buffer could always be achieved with ISEs). It was found that the detection limit of highly selective ISEs is often dictated by an elevated concentration of primary ion at the membrane surface that is generated from a zero current ion flux from the membrane into the sample. This flux often originates from the asymmetrical setup of the electrode, where a relatively concentrated inner solution is placed at the backside of the membrane. Even extremely small concentration gradients across the membrane can lead to a

significant ion flux that may concentration polarize the sample solution at the membrane surface. Today, the detection limit for numerous ISEs has been improved to nanomolar and sometimes even picomolar concentrations, placing this class of electrodes for the first time among the most sensitive electrochemical detection systems available.

## Introduction

A number of very important pollutants of the environment are gases, the most prominent of them being the oxides of nitrogen and sulfur; moreover, the content of carbon dioxide in the atmosphere is a highly significant factor affecting the global climate. Furthermore, determination or continuous monitoring of various gases is indispensable in industry, medicine, and many other fields. Consequently, simple, rapid, and reliable methods must be available for monitoring of gases. One of the choices is potentiometry using probes based on ion-selective electrodes (ISEs) and related sensors.

In general, any ion-selective potentiometric sensor can be used to monitor gases, provided that it is immersed in an electrolyte solution containing the ion sensed and whose activity changes on dissolution of the gas to be determined. Such a potentiometric cell, containing an indicating ion-selective sensor and a reference electrode immersed in an electrolyte, and

exchanging only gases with the environment to be analyzed, is termed the gas-sensing probe. In addition to these potentiometric probes with liquid electrolytes, solid-state gas sensors can be used that employ either solid electrolytes or are based on measurement of changes in the electrical parameters of semiconductors in the presence of a test gas.

Gas probes are used not only for monitoring of substances that are gaseous under normal ambient conditions, but also for determining solid compounds and compounds contained in solutions that are converted into gaseous products by a preceding (bio)chemical reaction; the latter determinations are advantageous in their high selectivity. Therefore, potentiometric gas probes are often used as sensing systems in biosensors.

## Principles

There are several experimental arrangements in potentiometric determination of gases.

### Determination in Gas-Stripping Solutions

This is the simplest system. The gaseous medium is passed through an absorption solution of an

significant ion flux that may concentration polarize the sample solution at the membrane surface. Today, the detection limit for numerous ISEs has been improved to nanomolar and sometimes even picomolar concentrations, placing this class of electrodes for the first time among the most sensitive electrochemical detection systems available.

## Introduction

A number of very important pollutants of the environment are gases, the most prominent of them being the oxides of nitrogen and sulfur; moreover, the content of carbon dioxide in the atmosphere is a highly significant factor affecting the global climate. Furthermore, determination or continuous monitoring of various gases is indispensable in industry, medicine, and many other fields. Consequently, simple, rapid, and reliable methods must be available for monitoring of gases. One of the choices is potentiometry using probes based on ion-selective electrodes (ISEs) and related sensors.

In general, any ion-selective potentiometric sensor can be used to monitor gases, provided that it is immersed in an electrolyte solution containing the ion sensed and whose activity changes on dissolution of the gas to be determined. Such a potentiometric cell, containing an indicating ion-selective sensor and a reference electrode immersed in an electrolyte, and

exchanging only gases with the environment to be analyzed, is termed the gas-sensing probe. In addition to these potentiometric probes with liquid electrolytes, solid-state gas sensors can be used that employ either solid electrolytes or are based on measurement of changes in the electrical parameters of semiconductors in the presence of a test gas.

Gas probes are used not only for monitoring of substances that are gaseous under normal ambient conditions, but also for determining solid compounds and compounds contained in solutions that are converted into gaseous products by a preceding (bio)chemical reaction; the latter determinations are advantageous in their high selectivity. Therefore, potentiometric gas probes are often used as sensing systems in biosensors.

## Principles

There are several experimental arrangements in potentiometric determination of gases.

### Determination in Gas-Stripping Solutions

This is the simplest system. The gaseous medium is passed through an absorption solution of an

electrolyte and the change in the solution composition is monitored with an ion-selective sensor, which is either directly immersed in the absorption vessel or is placed in a flow cell to which the absorption solution is fed by a pump. The advantages of this approach are the possibilities of preconcentration of the analyte in the absorption solution and the obtaining of integral concentration values of the analyte over a certain time period. On the other hand, the response is sluggish and the selectivity of determination may sometimes be unsatisfactory.

#### Determination with Sensors Separated from the Test Medium

This is the most common situation and three basic approaches are outlined below.

**Permeation units** The gaseous test substance is absorbed from the atmosphere (or generated from a nongaseous analyte by a (bio)chemical reaction) in a donor solution that is fed to a permeation unit containing a gas-permeable membrane separating the donor solution from an acceptor solution. The composition of the donor solution is chemically modified to liberate the gas again, the gas then permeates from the donor solution into the acceptor solution, and the latter, whose composition is suitable for potentiometric detection, is transported to the indicating sensor system. The gas-transfer efficiency depends on the gas partition coefficient between the two solutions, the gas mass-transfer rate through the membrane (i.e., on the kind of gas, membrane material, and membrane thickness), the relative velocities of the donor and acceptor solutions, and the membrane surface area. Hence, the solution composition can be independently optimized from the point of view of the gas absorption and the potentiometric detection; analyte preconcentration can be attained through optimization of the solution flow rates and selectivity of determination improved by combining the selectivities of the gas absorption (or generation), the gas transport through the membrane, and the potentiometric detection itself. These permeation units are especially useful in flow analyses (continuous monitoring, flow injection analysis, and continuous-flow analysis).

**Compact gas probes** In compact gas probes (combination electrodes), the ion-selective sensor is covered with a gas-permeable membrane enclosing a thin film of electrolyte containing the ion sensed (the Severinghaus-type probe, **Figure 1**). A gas from the test medium passes through the membrane, dissolves in the electrolyte film, and changes the activity of the ion sensed. The type of ion-selective sensor,

**Figure 1** A simplified scheme of the  $\text{CO}_2$  gas probe (Severinghaus type). 1, Detector body; 2, indicator electrode (pH glass electrode); 3, reference electrode; 4, internal electrolyte; 5, gas-permeable membrane; 6, medium analyzed; and 7, voltmeter (pH-meter). (The components of the probe are not drawn to a real scale.)

the electrolyte composition, and the kind of gas-permeable membrane are selected according to the test gas (e.g., some gases undergo proteolytic reactions in the electrolyte film resulting in a change in the pH which is sensed by a pH sensor). The analytical parameters of these probes are complex functions of many factors. The response time, selectivity,

sensitivity, and the limit of detection depend on the properties of the membrane (i.e., the permeability coefficient, which is the product of the gas diffusion coefficient in the membrane and the gas partition coefficient between the test medium and the membrane material, and the membrane thickness), on the composition, concentration, and thickness of the electrolyte film, on the sample matrix, and also on the analyte concentration. Therefore, the probe design and experimental conditions must always be optimized for given analytical problems.

As many analytically important gases are acidic or basic, the most common sensor is the glass pH ISE. The shape of the ISE sensing surface is important from the point of view of the quality of the electrolyte film, which is usually obtained by pressing the sensing part of the glass ISE immersed in an electrolyte solution on the gas-permeable membrane. The film should be as thin as possible, to decrease the response time – a mildly convex ISE sensing surface is most convenient for obtaining thin electrolyte films without dead spaces (Figure 1).

Two principal kinds of gas-permeable membrane are used, namely, homogeneous polymers through which the gas is transported by molecular diffusion after dissolution in the membrane material (typical diffusion coefficients are given in Table 1) and microporous membranes, where the pores are larger than the gas molecules and thus the test gas is transported by diffusion in the gaseous phase within the membrane pores. Homogeneous membranes may contribute to the measurement selectivity, but the mass transport through them is slow; from this point of view, silicone rubber membranes are advantageous, as the diffusion coefficients are relatively high (see Table 1).

Microporous membranes create virtually no diffusion barrier, since the gas diffusion coefficients in the gaseous phase are of the order of  $0.1 \text{ cm}^2 \text{ s}^{-1}$ . Hence, the response of probes with these membranes is

faster, but the membrane transport provides no selectivity and the diffusion geometry is not particularly stable. Microporous membranes must not be wetted by the solutions present, as the flooding of the membrane pores causes a drastic suppression of the probe response. Microporous membranes also permit passage of water vapor. If the water vapor pressures in the sample and the probe electrolyte film, and/or the sample and electrolyte temperatures are not equal, then water is transported through the membrane, the electrolyte film thickness and its concentration vary, and the signal drifts; when gases are monitored in the gaseous phase, the electrolyte film can dry up completely. The thinner the electrolyte film, the more pronounced are these effects.

Finally, the mechanical strength of the membrane must be considered, as the electrolyte film thickness and its reproducibility depend on the constancy and reproducibility of the pressure of the ISE on the membrane. Polytetrafluoroethylene, polypropylene, polyethylene, and silicone rubber are the most common membrane materials.

The composition of the electrolyte film depends on the kind of equilibrium reaction in which the gaseous analyte participates. The limits of detection (LODs) are commonly  $\sim 10^{-5}$ – $10^{-6} \text{ mol l}^{-1}$ . Decreasing the electrolyte concentration can decrease the LOD value, but then the dynamic range of the response is limited at higher analyte concentrations. Useful electrolyte concentrations range from  $10^{-2}$  to  $10^{-5} \text{ mol l}^{-1}$ .

The LOD value further depends on the kind and concentrations of the interferents present. The effect of interferents depends on the length of the measuring interval. During short-time measurements, the selectivity is primarily determined by the ratio of the permeability coefficients of the analyte and the interferents in the membrane material, while after a certain time, in steady state, it is given by the ratio of the dissociation constants of the analyte and the interferents in the electrolyte solution.

The response rate depends on the magnitude of the change in the analyte concentration and also on its direction. It increases with increasing magnitude of the analyte concentration change and is greater and more reproducible when the analyte concentration increases. In general, the time constants are rather high, ranging from tens of seconds to several minutes.

Replacement of glass pH electrodes by pH-sensitive and other ion-selective polymer membranes can be considered as an attempt at a fundamental change in the approach to the construction of membrane gas probes. The use of these membranes allows innovative structural designs leading to miniaturization and to mass production of low-cost

disposable detectors especially appreciated in clinical use. However, the parameters of the membranes tested have not met the requirements for routine use.

**Air-gap detectors** In air-gap detectors, the sensing electrode is separated by air from the test medium (Figure 2). These detectors are useful for analyses of substances in solution, after converting the analytes to gaseous products. The gaseous product passes from the solution into the air, diffuses to the sensing electrode, and dissolves in the film of an electrolyte solution covering the electrode surface. The electrolyte film on the sensor is obtained by touching the sensor surface, e.g., by a sponge soaked with the required electrolyte solution (Figure 2A), or a drop of an electrolyte is placed between a sensing and a

reference electrode (e.g., in the determination of cyanide, in which the sensing electrode – a silver wire, is connected with the tip of a reference electrode by a drop of a buffered solution of  $\text{KAg}(\text{CN})_2$  – Figure 2B).

**Detectors based on field-effect transistor** Ion-selective field effect transistor (ISFET) or chemically sensitive field effect transistor (CSFET) may replace classical ISE in Severinghaus-type gas-sensing probes; the use of pH-sensitive ISFETs is most common. Because of their small dimensions, ISFET-based gas-sensing systems have been tested for, e.g., in *in vivo* monitoring of the contents of a clinically important gas,  $\text{CO}_2$ , in blood. Similar to gas probes with polymeric ion-selective membranes, these systems have not yet found extensive use in practice. Direct detection of gases by FET sensors (e.g., using palladium-gate devices or electron work-function sensors) is advantageous and practically important, but the principles of these techniques are outside the field of ion-selective sensing.

## Determination of some Important Gases

The most common applications of membrane gas-sensing probes are summarized in Table 2.

### Nitrogen Oxides

The content of nitrogen oxides ( $\text{NO}_x$ ) in the air usually varies from 1 to over  $100 \mu\text{g m}^{-3}$ . The nitrogen dioxide ( $\text{NO}_2$ ) gas-sensing probe suffers from interferences and thus the nitrate ISE is used more often for determination, after suitable trapping and conversion of  $\text{NO}_x$ .

Nitrogen oxides can be chemisorbed on lead dioxide heated to  $190^\circ\text{C}$ , with formation of lead(II) nitrate, which is extracted into hot water and then measured with a nitrate ISE. Carbon dioxide, water

**Table 2** A survey of the most common membrane gas-probes (the probes for gases printed in bold letters are commercially available)

Gas	Principal component of the internal electrolyte	Equilibrium reaction	Indicator electrode
<b><math>\text{NO}_2</math></b>	$\text{NaNO}_3$	$2\text{NO}_2 + \text{H}_2\text{O} \rightleftharpoons 2\text{H}^+ + \text{NO}_3^- + \text{NO}_2^-$	Glass pH
<b><math>\text{SO}_2</math></b>	$\text{NaHSO}_3$	$\text{SO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}^+ + \text{HSO}_3^-$	Glass pH, antimony
<b><math>\text{CO}_2</math></b>	$\text{NaHCO}_3$	$\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}^+ + \text{HCO}_3^-$	Glass pH, antimony, $\text{CO}_3^{2-}$ ISE
<b><math>\text{NH}_3</math></b>	$\text{NH}_4\text{Cl}$	$\text{NH}_3 + \text{H}_2\text{O} \rightleftharpoons \text{NH}_4^+ + \text{OH}^-$	
	Me (Ag, Cu, Hg)	$n\text{NH}_3 + \text{Me}^{n+} \rightleftharpoons \text{Me}(\text{NH}_3)_n^+$	
$\text{H}_2\text{S}$	Buffer (pH 5)	$\text{H}_2\text{S} \rightleftharpoons \text{HS}^- + \text{H}^+$	
$\text{Cl}_2$	$\text{HSO}_3^-$ buffer	$\text{Cl}_2 + \text{H}_2\text{O} \rightleftharpoons \text{Cl}^- + 2\text{H}^+ + \text{ClO}^-$	
$\text{HCN}$	$\text{KAg}(\text{CN})_2$	$\text{Ag}(\text{CN})_2^- \rightleftharpoons \text{Ag}^+ + 2\text{CN}^-$	
$\text{HF}$	Acid	$\text{HF} \rightleftharpoons \text{H}^+ + \text{F}^-$	
	$\text{Fe}^{3+}/\text{Fe}^{2+}$	$\text{FeF}_x^{2-x} \rightleftharpoons \text{FeF}_y^{3-y} + (x-y)\text{F}^-$	
$\text{N}_3\text{H}$	$\text{NaN}_3 + \text{NaCl}$	$\text{N}_3\text{H} \rightleftharpoons \text{H}^+ + \text{N}_3^-$	

vapor, and nitrogen are not sorbed and possible interference from hydrogen chloride is eliminated by the addition of lead(II) fluoride; however, sulfur dioxide causes a positive error of determination when present at a more than 10-fold excess over  $\text{NO}_x$ .

Another way of selectively trapping  $\text{NO}_x$  is oxidative absorption, e.g., by passing air through a 2% hydrogen peroxide solution for 24 h at a flow rate of  $2 \text{ l min}^{-1}$ . Excess hydrogen peroxide is removed by adding manganese dioxide and the nitrate formed in the absorption solution is determined with a nitrate ISE; sulfur dioxide does not interfere up to a 40-fold excess. These methods are, of course, not quite adequate for continuous sensing.

A personal  $\text{NO}_x$  dosimeter employs trapping of the gases on a glass filter impregnated with sodium dichromate and sulfuric acid ( $\text{NO}$  is oxidized to  $\text{NO}_2$ ), followed by passage of the  $\text{NO}_2$  through a silicone rubber membrane into an acidic solution of hydrogen peroxide in which nitrate is formed and measured by a nitrate ISE.

Nitrogen dioxide can also be selectively detected by an electrode with a chalcogenide ( $\text{Se}_{60}\text{Ge}_{28}\text{Sb}_{12}$ ) membrane, without interference from nitric oxide, sulfur dioxide, carbon monoxide, methane, and other gases. Another solid-state sensor for  $\text{NO}_2$  employs an alkaline nitrate electrolyte at a temperature of  $800^\circ\text{C}$ .

### Sulfur Dioxide

The content of sulfur dioxide ( $\text{SO}_2$ ) in the atmosphere varies widely and may reach values as high as  $1\text{--}5 \text{ mg m}^{-3}$  in heavily polluted air. Direct monitoring with an  $\text{SO}_2$  gas probe is often insufficiently sensitive and thus  $\text{SO}_2$  must be preconcentrated by absorption in a suitable solution. The most common procedure is based on absorption of  $\text{SO}_2$  in a tetrachloromercurate(II) solution (TCM), in which  $\text{Hg}(\text{SO}_3)_2^{2-}$  is formed. The pH of the absorption solution is maintained at a value of 6.9 that ensures virtually complete absorption of  $\text{SO}_2$ . Prior to analysis, amidosulfonic acid is added to remove nitrite and the pH is decreased to about unity, so that most of the sulfite present is converted into free sulfur dioxide, which is determined by an  $\text{SO}_2$  probe. With very low  $\text{SO}_2$  contents, a filter is soaked with a TCM solution and air is passed through the filter at a high flow rate and for a rather long time. These methods provide discontinuous values of the  $\text{SO}_2$  concentration in regular intervals.

Other possibilities include absorption of  $\text{SO}_2$  in a 3% solution of hydrogen peroxide followed by titration of the solution with a lead(II) standard solution (indication – lead(II) ISE), or the reduction of iodine by  $\text{SO}_2$  with determination of the iodide formed with an iodide ISE.

A solid-state sensor employs a solid alkali sulfate electrolyte at an elevated temperature ( $800^\circ\text{C}$ ).

### Carbon Dioxide

The gas-sensing probe for carbon dioxide ( $\text{CO}_2$ ) is the original Severinghaus sensor. The dynamic range of this determination is rather limited and the limit of detection is  $\sim 10^{-4} \text{ mol l}^{-1}$ , as the concentration of atmospheric  $\text{CO}_2$  dissolved in water is  $1\text{--}3 \times 10^{-5} \text{ mol l}^{-1}$ .

### Other Important Gases

Ammonia is best determined with a gas-sensitive probe (see Table 2), which is highly selective and exhibits a limit of detection of above  $5 \times 10^{-7} \text{ mol l}^{-1}$ . Volatile amines may interfere in the determination. When determining ammoniacal nitrogen in solution, the test solution is made alkaline ( $\text{pH} \geq 11.2$ ), so that the  $[\text{NH}_4^+]/[\text{NH}_3]$  ratio is  $< 100$  and acidic gases (such as carbon dioxide, sulfur dioxide, and hydrogen sulfide) are converted into the corresponding anions and cannot interfere by diffusion through the probe membrane. The use of an air-gap sensor for ammonia prevents certain interferences, e.g., from surfactants when determining ammoniacal nitrogen in waste waters.

Hydrogen sulfide can be absorbed in an alkaline aqueous solution and then determined with a high sensitivity by a sulfide ISE (LOD of  $\mu\text{g m}^{-3}$  in the atmosphere). Sensors based on chalcogenide membranes have been also tested for the detection of  $\text{H}_2\text{S}$ . The solutions containing hydrogen sulfide must be protected against atmospheric oxidation.

Chlorine can be determined using a gas-sensitive probe (Table 2) or by absorption in an  $\text{Ag}(\text{CN})_2^-$  solution and measurement with an iodide ISE or, better, a sulfide ISE.

Hydrogen fluoride is determined either by a gas probe (Table 2), or, more often, by a fluoride ISE (lanthanum fluoride based) after absorption in a suitable medium. Hydrogen fluoride emissions can be measured down to a content of  $0.1 \mu\text{g m}^{-3}$ .

### Introduction

Potentiometric enzyme electrodes form a large group of catalytic biosensors, resulting from a thin layer of enzyme integrated within or intimately associated with a potentiometric transducer. The enzyme generates a reaction that enables determination of the substrate (the target analyte), providing a highly selective and sensitive method for the determination of a given, ionic or nonionic, substrate. The determination of the electrode potential gives a direct indication of the concentration of the analyte. The signal obtained is proportional to the logarithm of the concentration, following the Nernst law.

### General Features of Enzyme Electrodes

#### Potentiometric Transducers

Guilbault and Montalvo were the first, in 1969, to detail a potentiometric enzyme electrode. They described a urea biosensor based on urease immobilized at an ammonium-selective liquid membrane electrode. Since then, over hundreds of different applications have appeared in the literature, due to the significant development of ion-selective electrodes (ISEs) observed during the last 30 years. The electrodes used to assemble a potentiometric biosensor include glass electrodes for the measurement of pH or monovalent ions, ISEs sensitive to anions or cations, gas electrodes such as the CO<sub>2</sub> or the NH<sub>3</sub> probes, and metal electrodes able to detect redox species; some of these electrodes useful in the construction of potentiometric enzyme electrodes are listed in Table 1.

In the 1980s, ion-selective membranes were used for the first time as the molecular recognition element

of sensors based on field-effect transistor (so called ion-selective field-effect transistor, ISFET).

Nowadays, ion-selective sensors are constructed using various advanced methods such as thick- and thin-film technology. A thick-film sensor comprises layers of special pastes (thickness 10–50 µm) deposited onto an insulating substrate; the method of film deposition is the screen-printing technique. Thin-film electrochemical transducers are built up by the successive deposition and patterning of dielectric and conductive materials, on top of an optically flat and polished substrate. The deposition of the thin metallic films (thickness 10–200 nm) is generally carried out by classical evaporation or sputtering of a solid metal source; then, photolithography and other techniques can be envisaged to pattern the electrode material. Using these technologies, microfabricated arrays of sensors and biosensors have been developed.

Interesting features of potentiometric transducers are simplicity of instrumentation (only a potentiometer is needed), low cost, selectivity, and the non-destructive nature of the analytical procedure.

#### Biosensor Assembly

In order to prepare the biosensor, the enzyme has to be immobilized in the form of a thin layer at the surface of the transducer. Among the several methods for immobilization available, the following are the most generally employed: (1) physical entrapment within an inert polymeric membrane (in this case the enzyme is mixed with a monomer solution, which is then polymerized to a gel – polyacrylamide gel, starch, agar gel, etc., thus trapping the enzyme) or behind a membrane (in this case the enzyme solution is simply confined by an analyte permeable membrane, such as a dialysis membrane, as a thin film covering the indicator electrode; this method is also called micro-encapsulation); (2) covalent bonding of the enzymes on membranes or surfaces activated by means of bi-functional groups or spacers, such as glutaraldehyde, carbodiimide (when the enzyme is bound to the solid support using a bi- or multifunctional agent, such as

### Introduction

Potentiometric enzyme electrodes form a large group of catalytic biosensors, resulting from a thin layer of enzyme integrated within or intimately associated with a potentiometric transducer. The enzyme generates a reaction that enables determination of the substrate (the target analyte), providing a highly selective and sensitive method for the determination of a given, ionic or nonionic, substrate. The determination of the electrode potential gives a direct indication of the concentration of the analyte. The signal obtained is proportional to the logarithm of the concentration, following the Nernst law.

### General Features of Enzyme Electrodes

#### Potentiometric Transducers

Guilbault and Montalvo were the first, in 1969, to detail a potentiometric enzyme electrode. They described a urea biosensor based on urease immobilized at an ammonium-selective liquid membrane electrode. Since then, over hundreds of different applications have appeared in the literature, due to the significant development of ion-selective electrodes (ISEs) observed during the last 30 years. The electrodes used to assemble a potentiometric biosensor include glass electrodes for the measurement of pH or monovalent ions, ISEs sensitive to anions or cations, gas electrodes such as the CO<sub>2</sub> or the NH<sub>3</sub> probes, and metal electrodes able to detect redox species; some of these electrodes useful in the construction of potentiometric enzyme electrodes are listed in Table 1.

In the 1980s, ion-selective membranes were used for the first time as the molecular recognition element

of sensors based on field-effect transistor (so called ion-selective field-effect transistor, ISFET).

Nowadays, ion-selective sensors are constructed using various advanced methods such as thick- and thin-film technology. A thick-film sensor comprises layers of special pastes (thickness 10–50 µm) deposited onto an insulating substrate; the method of film deposition is the screen-printing technique. Thin-film electrochemical transducers are built up by the successive deposition and patterning of dielectric and conductive materials, on top of an optically flat and polished substrate. The deposition of the thin metallic films (thickness 10–200 nm) is generally carried out by classical evaporation or sputtering of a solid metal source; then, photolithography and other techniques can be envisaged to pattern the electrode material. Using these technologies, microfabricated arrays of sensors and biosensors have been developed.

Interesting features of potentiometric transducers are simplicity of instrumentation (only a potentiometer is needed), low cost, selectivity, and the non-destructive nature of the analytical procedure.

#### Biosensor Assembly

In order to prepare the biosensor, the enzyme has to be immobilized in the form of a thin layer at the surface of the transducer. Among the several methods for immobilization available, the following are the most generally employed: (1) physical entrapment within an inert polymeric membrane (in this case the enzyme is mixed with a monomer solution, which is then polymerized to a gel – polyacrylamide gel, starch, agar gel, etc., thus trapping the enzyme) or behind a membrane (in this case the enzyme solution is simply confined by an analyte permeable membrane, such as a dialysis membrane, as a thin film covering the indicator electrode; this method is also called micro-encapsulation); (2) covalent bonding of the enzymes on membranes or surfaces activated by means of bi-functional groups or spacers, such as glutaraldehyde, carbodiimide (when the enzyme is bound to the solid support using a bi- or multifunctional agent, such as

**Table 1** Potentiometric enzyme electrodes

<i>Electrochemical sensor</i>	<i>Enzyme</i>	<i>Metabolite</i>	<i>Measurement range (mmol l<sup>-1</sup>)</i>
Glass, pH	Urease	Urea	0.05–5

gluteraldehyde, which forms a bridge between biocatalytic species or proteins, the technique is also called cross-linking or reticulation); and (3) immobilization on commercially available activated membranes such as Immudodyne produced by Pall Industries, or Ultra-Bind produced by Gelman Sciences.

Several enzymes can be immobilized within the same reaction layer, in order to increase the range of possible biosensor analytes, provide efficient regeneration of enzyme cosubstrates, or to improve the biosensor selectivity by decreasing the local concentration of electrochemical interfering substances.

Generally, the technique of chemical immobilization (covalent bonding) is preferred. This procedure improves the enzyme stability and defines a diffusion layer where the product, formed by the catalytic action of the enzyme, diffuses partly to the electrode surface and partly back to the bulk of the solution; therefore, by defining the steady state one obtains a reproducible potential value. However, the real advantage of the enzyme immobilization through chemical bonding is the lifetime of the final probe, which can reach 6–12 months.

An enzyme electrode operates via a five-step process: (1) transport of the substrate to the surface of the

electrode; (2) diffusion of the substrate through the membrane to the enzyme-active site; (3) a reaction occurring at the active site; (4) product formation in the enzymatic reaction and its transport through the membrane to the surface of the electrode; and (5) measurement of the product at the electrode surface.

The first step, transport of the substrate, is most critically dependent on the stirring rate of the solution, so that rapid stirring will bring the substrate very rapidly to the electrode surface. If the membrane is kept very thin using highly active enzymes, then steps (2) and (4) are eliminated or minimized; since step (3) is very fast, the response of an enzyme electrode should theoretically approach the response time of the base sensor. Many researchers have shown experimentally that one can approach this behavior using a thin membrane and rapid stirring.

## Analytical Features of Enzyme Electrodes

### Concentration Range

The maximum concentration of substrate that can be measured with an enzyme electrode is governed by  $K_m$  (the Michaelis–Menten constant). If the

**Table 2**  $K_m$  values reported for soluble enzymes and maximum concentration values of the linear concentration range reported for each biosensor probe

Enzyme	Substrate	$K_m$ (mmol l <sup>-1</sup> )	Concentration value (mmol l <sup>-1</sup> )
Urease	Urea	10	10
Glucose oxidase	Glucose	7.7	35
L-Amino acid oxidase	Leucine	1.0	10
Invertase	Sucrose	0.45	1
Alkaline phosphatase	<i>p</i> -Nitrophenylphosphate	0.1	1
Lactate oxidase	Lactate	0.7	20
Pyruvate oxidase	Pyruvate	1.7	2
Creatininase	Creatinine	0.33	1
Acetylcholinesterase	Acetylcholine	0.09	1
Uricase	Uric acid	0.017	1

concentration is near to  $K_m$ , the linear relation between substrate concentration and the extent of enzyme reaction fails and a limiting value is reached. However, the picture is not always as straightforward as this. Table 2 lists the maximum concentration values of substrates measured with enzyme probes and compares them with  $K_m$  data for soluble enzymes. In general, the maximum concentration of a substrate exceeds the  $K_m$  value by approximately one order of magnitude.

The difficulty of measuring high concentration is usually overcome by diluting the sample. This procedure has the advantage of the control of pH and ionic strength by the use of suitable buffers, so that samples and standards are measured under identical conditions.

Immobilization of the enzyme is thought to increase the  $K_m$  value, the increase being related to change of substrate/carrier, diffusion effects, or changes in enzyme structure.

The minimum concentration is often related to the minimum amount of electroactive substance that can be measured with the electrochemical probe. Generally, with ISE or gas potentiometric probes the limit of concentration measurable is  $10^{-5}$  mol l<sup>-1</sup>. The calibration graphs are therefore often S-shaped, leveling off at high concentration due to the  $K_m$  or  $K_m$ -related maximum concentration measurable and at low values by the performances of the potentiometric base probe (Figure 1).

One of the most important parameters concerning the concentration range is the activity of the enzyme in the membrane layer. As a general rule, the slope of the sensor will increase with increasing amount of enzyme up to a limiting value. The activity of the enzyme determines the percentage of reaction of the substrate, and hence the amount of electroactive species. However, with increasing amounts of enzyme loading, the percentage of substrate reacting reaches a limit that matches its complete transformation.

**Figure 1** Calibration of a potentiometric urease electrode for urea. Curves are related to different loadings.

The amount of enzyme to be used depends on the immobilization procedure and on the enzyme purity. As a rule of thumb,  $\sim 10$ – $20$  IU per membrane is generally sufficient to give an excellent response. For the less stable, soluble, and physically entrapped enzyme electrodes, an excess of enzyme should be used, that is,  $50$  IU cm<sup>-2</sup> of electrode surface, so that a loss of enzyme does not affect the observed responses. Likewise, purified enzymes should be used so as to promote fast response rates.

### Response Time

Mathematical models describing response times have been considered in the literature. This is the essential feature of an assembled probe, and depends on the procedure of assembling the probe, specifically on the method of immobilization, the electrochemical probe employed, the geometry of the measuring cell, and the kinetics of the enzymatic reaction.

### Diffusion of Substrate

The difference in response between an unstirred solution and a stirred one can decrease the response time from 10 to 1–2 min or less. Also, the potential is

a function of stirring rate related to the amount of substance brought to the electrode surface and to its reactivity. Hence, for fast response times and steady states, a fast but constant rate of stirring of the substrate solution is recommended.

### Substrate Concentration

The rate of enzymatic reaction increases with substrate concentration; for example, in the case of a cyanide electrode coupled with immobilized  $\beta$ -glucosidase enzyme, a response time of 20 s for  $10^{-1} \text{ mol l}^{-1}$  amygdalin and 1 min for  $10^{-4} \text{ mol l}^{-1}$  amygdalin is obtained. Rather than waiting until an equilibrium potential is reached, the rate of potential change ( $\Delta E/\Delta t$ ) can be measured, the result being proportional to substrate concentration.

### Enzyme Concentration

There is a twofold effect on increasing the enzyme activity in the layer that is in close proximity to the electrode surface. First, a complete conversion of the substrate into products will be ensured; second, the response time of the electrode will be affected. The increase in the amount of enzyme affects the thickness of the membrane. This results in an increase in the time required for the substrate to diffuse through the membrane. Hence, for the best results, it is recommended that an enzyme of as high an activity as possible is used in order to ensure rapid kinetics by achieving the thinnest possible membrane.

### pH Effect

Every enzyme has an optimum pH at which it is most active and a certain pH range within which it does not exhibit reactivity. The pH ranges of immobilized enzymes are different from those of soluble enzymes because of the microenvironment. Highly negatively charged carriers create a lower pH at the boundary layer between the carrier and the bulk solution. Thus, the enzyme is in a more acidic environment than the bulk solution. The reverse occurs with positively charged supports. Even for uncharged supports, the overall charges of the enzyme may be sufficient to cause changes in the apparent pH optimum. However, in general, the greater the charge on the support, the greater is the effect, particularly with charged substrates. The optimum pH should be used for obtaining the fastest response, but this is not always possible because the electrode sensor may not itself give the optimum response at the pH of the enzyme reaction. Therefore, a compromise is usually necessary. This is especially important for the ammonia and carbon dioxide electrodes. For ammonia electrochemical sensors, samples should have a pH

>9 in order to obtain complete conversion of  $\text{NH}_4^+$  into  $\text{NH}_3$ , and to obtain a shorter response time of the electrochemical probe. However, few enzymes can function at such high pH, so a compromise is necessary. With the carbon dioxide sensor, the samples should be kept at  $\text{pH} < 5$  to obtain a complete conversion to carbon dioxide of hydrogencarbonate; however, these low pH values often interfere with the enzyme reaction, and a compromise is necessary between optimum pH for enzyme activity and optimum pH range of response of the probe.

### Temperature Effect

The effect of increasing temperature is twofold: an increase in the rate of reaction gives faster response time and a shift in the equilibrium value due to variations in the equilibrium constant. Electrochemical sensors of the gas-permeable membrane type (ammonia and carbon dioxide) lead to an additional effect, since the gas membrane and the features of the diffusion are sensitive to temperature variations. Despite the above considerations, a classical bell-shaped curve is almost always obtained when recording the response of the probe as function of temperature. Room temperature, or  $25^\circ\text{C}$  (controlled to  $\pm 0.2^\circ\text{C}$  is recommended), is often employed when using an electrochemical probe, although when using a gas permeable membrane control to  $\pm 0.1^\circ\text{C}$  is required.

### Thickness of the Enzyme Membrane

The time required to reach steady-state potential reading is dependent on the enzyme layer thickness because of the diffusion parameter for the substrate to reach the active sites of the enzyme and of the electroactive species to diffuse through the membrane to the sensor. A mathematical model relating the thickness of the membrane,  $d$ , the diffusion coefficient,  $D$ , the Michaelis constant,  $K_m$ , and the maximum velocity of the enzyme reaction,  $V_{\max}$ , has been developed:

$$V_{\max}d^2/DK_m = V$$

where  $V$  compares the rate of chemical reaction in the membrane with the rate of diffusion through the membrane. Larger  $V$  indicates faster enzyme catalysis relative to the diffusion process.

Membranes as thin as possible are recommended for the best results, and this is helped by the use of a highly active enzyme.

### Effect of Additional Membranes

Besides the enzymatic reacting layer, many biosensors, especially designed for biological or clinical

applications, incorporate one or more membranes, which serve mainly two important functions: (1) Protective barrier: to prevent the interference of molecules, such as proteins or cells of biological samples, with the reaction layer or to decrease the influence of electrochemical species detected by the transducer. It also reduces leakage of the reacting layer components into the sample solution. (2) Diffusional outer barrier for the substrate: the linear dynamic ranges may be large if the sensor response is controlled by the substrate diffusion through the membrane and not by the enzyme kinetics. This is achieved by placing a thin outer membrane over a highly active enzyme layer.

Generally, the thinner the membranes, the shorter is the biosensor response time.

### Electrode Probe

A limiting factor on the speed of response of an enzyme-based electrode is the response time of the base electrode. Electrodes based on gas-permeable membranes (ammonia or carbon dioxide) have longer response times than those without such membranes (ISEs, pH glass electrodes, ISFETs). In both cases, the response time of the electrode is the limiting factor at low substrate concentration. Response times of the order of 10–30 s can easily be obtained for concentrations in the range  $0.1\text{--}1\text{ mmol l}^{-1}$ .

### Washing Time of Probe

Because of a build-up of product in the enzyme membrane, enzyme electrodes require washing prior to contact with the next sample. The washing time varies from just 20 s for urease in conjunction with an ammonia electrode to as long as 10 min for urease with a pH electrode. The washing time increases with enzyme membrane thickness, as also observed for additional membranes discussed above. It will also depend on the enzyme used and on the characteristic of the base sensor itself, and will be affected by diffusion and kinetic effects. The use of flow injection analysis simplifies the procedures, since the carrier stream serves to wash out between samples.

Deterioration of the enzyme electrode can be seen in three changes in the response characteristics: (1) with age the upper limit will decrease from  $\sim 10^{-1}$  to  $10^{-2}\text{ mol l}^{-1}$ ; (2) the slope of the calibration curve of potential versus  $\log(\text{concentration})$ , 59 mV per decade, Nernstian, will drop to 50, 40, or perhaps 30 mV per decade or lower; (3) the response time of the electrode, originally 30 s to 2 min (approximately the same as that of the base sensor), will become longer as the enzyme ages.

### Interference Effects

For each enzyme-based sensor interferences fall into two categories, namely interference of the electrochemical probe and interference with the enzyme reaction.

#### Interference of the Electrochemical Probe

In the development of a urea electrode, the first approach was the use of a cation glass electrode, but the resulting probe could not be used for assaying urea in blood and urine because the sensor responded to sodium and potassium ions.

The sensor was improved by using the non-actin-based ammonium ISE. This ionophore has selectivity constants  $K_{\text{NH}_4, \text{K}}$  of 0.15 and  $K_{\text{NH}_4, \text{Na}}$  of  $1.3 \times 10^{-3}$ , thus partially eliminating the response of these ions by the sensor. Several articles have been published on this principle, taking into account the residual effect of sodium and potassium.

By using an ammonia electrode with a gas-permeable membrane that effectively excludes ions, it is possible to obtain the desired selectivity. Several assemblies have been studied to obtain rapid and reliable sensors.

The carbon dioxide probe can be used as a transducer for urea (Table 1); it is selective because the gas-permeable membrane excludes ions and other chemicals. However, many samples, especially in biological or clinical chemistry, have large levels of bicarbonate, which will interfere with this probe.

ISEs display different problems of interference when used as enzyme-based probes. In the cyanide sensor for amygdalin, sulfide can interfere, while an iodide electrode used for measuring glucose is susceptible to the presence of thiocyanate, sulfide, cyanide, and silver ions. Moreover, oxidizable compounds present in blood (e.g., uric acid, tyrosine, ascorbic acid, and iron(II)) compete for hydrogen peroxide. These compounds need to be removed by sample pretreatment. Finally, with regard to pH electrodes coupled to enzymes (Table 1), any acidic or basic component will interfere, as will a variable buffer capacity as found in clinical and biological samples. However, by adjusting the pH before initiating the enzyme reaction, and assuming that only the enzyme reaction will give a pH change, the effects can be minimized.

#### Interferences with the Enzyme Reaction

These fall into two classes, namely those where other substrates are present in the sample and those involving base enzyme activation or inhibition. With some enzymes, such as urease, the only substrate that reacts at a reasonable rate is urea; hence, a urease electrode is almost specific for urea. Likewise, uricase is almost specific for uric acid.

Others, such as penicillinase, will promote the reaction of many substrates. Thus, ampicillin, nafcillin, penicillin G, penicillin V, cyclibillin, and dicloxacillin can be determined with a penicillinase electrode. D- and L-amino acid oxidases are even less selective. The former, when coupled to an electrode, responds to D-phenylalanine, D-alanine, D-valine, D-methionine, D-leucine, D-norleucine, and D-isoleucine, while the latter responds to L-leucine, L-tyrosine, L-phenylalanine, L-tryptophan, and methionine.

For samples containing several substrates, a preliminary separation should be considered or the total must be determined. In the case of L-amino acid assay the use of decarboxylating enzymes acting selectively on different amino acids is an attractive possibility, and enzyme electrodes of this type are known for L-tyrosine, L-phenylalanine, and L-tryptophan. These sensors will be coupled with a carbon dioxide base sensor.

Enzyme inhibitors also need to be taken into account. These include heavy metal ions, such as silver, mercury, and sulfhydryl-reacting organic compounds, such as *p*-chloromercuribenzoate (due to their reaction with the free S-H groups at the active site of many enzymes, especially the oxidases).

## Examples of Enzyme Electrodes Based on ISEs

Table 1 lists enzyme electrodes that have been prepared for analysis of common substrates together with the enzyme used, the sensor, and the range of concentrations determinable. The most important features of some of these are described here.

### Urea

Urea is a diagnostic indicator for kidney function. Urea can be potentiometrically determined following the enzymatic reaction of the enzyme urease (reaction [I]) coupled with a variety of potentiometric transducers such as the  $p\text{CO}_2$  electrode, the  $p\text{NH}_3$  electrode, the pH electrode, and the  $p\text{NH}_4$  electrode:

The products of the enzymatic reaction given above also dissociate:

The first urea electrode was prepared in 1969 by immobilizing urease in a polyacrylamide matrix on nylon or Dacron nets. These nets were then placed onto a glass cation-selective electrode. To improve the selectivity, an ammonium-ion selective electrode with

nonactin, a neutral carrier, as the base sensor, together with immobilized urease in a polyacrylic gel was used.

### Creatinine

Creatinine is another diagnostic indicator of kidney function. Creatinine can be measured immobilizing purified creatininase (reaction [II]) onto nylon net and coupling it with an ammonia gas electrode:

The residual ammonia of blood serum can be removed using an enzyme reactor system, consisting of soluble NADPH and  $\alpha$ -ketoglutarate, with glutamate dehydrogenase immobilized on nylon tubes; this system is effective in removing 98% of the ammonia present in human blood and urine samples in 50 s. The entire process was carried out in a single flow stream.

### Glucose and Sugar Electrodes

An iodide-selective electrode can be used to measure glucose concentration. The measurement is based on reactions catalyzed by glucose oxidase (GOx) (reaction [III]) and peroxidase (POx) (reaction [IV]):

The highly sensitive iodide sensor monitors the decrease in the iodide activity at the electrode surface. The assay of glucose was performed both in a stream and at a stationary electrode. Pretreatment of the blood sample was required to remove interfering reducing agents such as ascorbic acid, tyrosine, and uric acid.

Moreover, pH electrodes can be used to detect the gluconic acid formed by the GOx reaction.

### Amino Acids

Enzyme electrodes have been widely used for the assay of amino acids in clinical analysis since several amino acids (tyrosine, phenylalanine, tryptophan, methionine) are important diagnostic health indicators.

The transducer can be an ammonium ISE ionophore (nonactin-based), a gas sensor for ammonia or carbon dioxide, and an iodide-selective sensor. The latter can be coupled with the enzymes L-aminooxidase (L-AOx) and peroxidase (e.g., coimmobilized in a polyacrylamide gel), which catalyses reactions [V] and [VI]:

Specific sensors for phenylalanine, tyrosine, glutamine, lysine, and methionine have been described in the literature.

## Penicillin

Penicillin is determined by cleaving the amide bond of the  $\beta$ -lactame ring with penicillase to produce penicilloic acid. This acid is detectable by a pH electrode covered with a thin film of penicillase and the biosensor produced was used to monitor penicillin concentration in many different fermentation broths.

## Neurotransmitters

Neurotransmitters may be determined using the respective hydrolases. Acetylcholine is hydrolyzed by acetylcholinesterase (AChE) according to reaction [VII]:

which can be monitored by immobilizing AChE on a pH electrode.

## Inhibitor-Sensitive Potentiometric Enzyme Electrodes

Some examples of potentiometric enzyme electrodes have been developed for indirect monitoring of organic pesticides or inorganic (heavy metals, fluoride, cyanide, etc.) substances that reduce the activity of the immobilized enzyme on the transducer. Parameters such as enzyme concentration, substrate concentration, pH, incubation time can affect the biosensor response, and have to be optimized. A classical example is the monitoring of organophosphorous and carbamate pesticides (whose mechanism of action is the inhibition of AChE, the enzyme implicated in the neurotransmission) using a glass electrode with immobilized AChE.

Heavy metals and fluoride ions have been reported to inhibit the activity of the enzyme urease.

## Introduction

An ion-selective electrode (ISE) is a chemical sensor that can quantitatively and reversibly measure an ion activity based on a potentiometric transduction of

the recognition process. Fiber optical sensors have been developed in response to the need for selective, reliable sensors for medical use, especially for patient-near offline or continuous *in vivo* monitoring, related to the problems inherent in electrochemical methods. Also, optical test kits for blood ions are commercially available. However, electrodes offer a broad field of applications in patient-near-monitoring as well as in large automated biochemistry analyzers.

Ion-selective electrodes introduced in chemical instruments are most frequently based on liquid

membranes incorporating natural or specifically tailored synthetic carriers, which accomplish the recognition process, as well as sodium glass membranes. Liquid membranes with a polymer matrix stabilizing the membrane phase were introduced in clinical chemistry in 1972 by Simon, where the first valinomycin electrode was tested in the University Hospital, Zurich, Switzerland. Solid-state sensors were introduced in 1980 for sodium chloride measurements in sweat preferably for the diagnosis of cystic fibrosis. Slide techniques for electrolyte assays were introduced subsequently for analyzers as well as for patient-near-monitoring.

Liquid-membrane electrodes are classified in two groups:

1. Liquid-membrane electrodes based on charged sites (classical ion exchanger or charged ion-selective complexing agent (charged ion carrier, charged ionophores)). The membrane consists of an organic, water-immiscible liquid phase incorporating sites.

2. Neutral carrier liquid- or solvent-polymeric membrane electrodes, in which the membrane is usually formed from an organic solution of an electrically neutral, ion-selective complexing agent (neutral ion carriers, neutral ionophores) held in an inert polymer matrix. These membrane electrodes make use of the outstanding inherent ion selectivity of certain natural and synthetic ionophores.

Electrolyte solutions contain at least two classes of mobile ions, namely cations and anions, and the membranes are not ideally permselective. Thus, a perfect exclusion of interfering species cannot be realized in practice. If considerations are restricted to permselective membranes for the ion I with relative activity  $a_i'$  in the sample phase, charge number  $z_i$ , and interfering ions J with charge number  $z_j$ , the description of the e.m.f. function of a membrane cell is ideally consistent with the classical Nikolsky-Eisenman equation:

$$\text{e.m.f.} = E = E_i^0 + \frac{RT}{z_i F} \ln \left[ a_i' + \sum_{j \neq i} K_{ij}^{\text{Pot}} a_j^{z_i/z_j} \right] \quad [1]$$

where  $RT/z_i F$  is the slope  $s$  of the electrode function denoted by the gas constant  $R$ , the Faraday constant  $F$ , the absolute temperature  $T$ , and the charge number of the primary ion  $z_i$ .  $E_i^0$  is a constant contribution to the e.m.f. The selectivity factor  $K_{ij}^{\text{Pot}}$  denotes a factor for the rejection of each interfering ion J within the sample solution in terms of relative ion activities  $a_j$  with charge number  $z_j$ . The relative activity  $a_i$  denotes the active molality of the ion I,  $m_i$  divided by unit molality:  $m_i/1 \text{ mol kg}^{-1}$ .

## Electrode Characteristics

### Electrode Standard Potential and Liquid Junction Potential

The electrode standard potential  $E_i^0$  corresponds to the intercept of the linear response function of the electrode, which is the e.m.f. change as a function of the logarithm of the relative ion activity ( $\Delta \text{e.m.f.} = f(\log a_i)$ ) and should be constant. The electrode standard potential  $E_i^0$  represents the sum of all contributions to the e.m.f. that are not immediately dependent on the activity of the primary ion I or the interfering ion J of the sample:

$$E_i^0 = E_{\text{Ref}} + E_J + E_{\text{el}} + E_{\text{as}} \quad [2]$$

For biological samples four different contributions to the standard potential  $E_i^0$  can be observed: the contribution of the internal standard potential of the reference electrode  $E_{\text{Ref}}$ ; the diffusion potential over the liquid junction  $E_J$  generated between the sample solution and the reference electrode; a potential difference (electrical asymmetry) of the ion-selective membrane after preparation and conditioning  $E_{\text{el}}$ ; and a sample-induced asymmetry of the membrane  $E_{\text{as}}$ . For measurements in human blood samples directly the adsorption of sample components at the membrane surface creates a drift associated with the affinity of the membrane to lipids as well as proteins.

Measuring techniques recommended by the Working Group on Sensors and Electrodes as well as membrane technological operations intend to compensate or eliminate these asymmetries responsible for inaccuracies by permanent recalibration. The extent of the sample-induced membrane asymmetry depends on the composition of the membrane and should be checked in a symmetric cell configuration for different applications. In a first approximation it is assumed that the potential of the reference electrode ( $E_{\text{Ref}} + E_J$ ), including the liquid junction potential, is constant and  $E_J$  is independent of the sample composition. Changes are minimized by the use of highly concentrated equitransferent reference solutions. However, the ideal behavior is usually not attained for various reasons. The liquid junction potential does in fact change considerably, e.g., due to the different ion background of calibrating solutions as compared to real samples (cations added as chlorides). An e.m.f. shift corresponding to 2–8% ion activity units may be observed. The electrode function may be corrected by calculation of  $E_J$  based on the Henderson equation and the background ion activities. The response of the liquid junction potential of the reference electrode versus proteins and lipids is very much influenced by the construction of the reference electrode.

**Selectivity Factor  $K_{ij}^{\text{Pot}}$** 

The selectivity of an electrode has to be discussed and checked within the dynamic range of activity of the analyte and the interfering ions relevant for medical assays.

A lack of discrimination of ions is measured as inaccuracy, which amounts to the difference between zero activity of the interfering ion and the mean actual activity, and as imprecision of the calibrated setting point due to the varying background ion activity. The variation around the calibrated setting point has to be restricted to less than the total allowable analytical error with respect to a reliable medical interpretation of the results for the primary ion. The allowable analytical error is defined by the biological variation of the analyte (see **Tables 1** and **2**) assuming absence of any inaccuracy. The same rules may be applied to the calculation of the required selectivity coefficient with regard to the necessary discrimination of interfering species. With first priority the required selectivity

coefficient is calculated based on the biological variation ( $cv_a \leq 0.5 cv_b$ ) or maximum 1% in second priority:

$$K_{ij}^{\text{Pot}} \leq 0.5 cv_b \cdot (a_i/a_j^{z_i/z_j}) = cv_a \cdot (a_i/a_j^{z_i/z_j}) \quad [3]$$

where  $cv_b$  is the biological coefficient of variation and  $cv_a$  is the analytical coefficient of variation. Unfortunately,  $cv_b$  has not yet been evaluated for ion activities. The required selectivity coefficients for a large physiological concentration range are presented in **Table 3** based on the intraindividual  $cv_b$  for total ion concentrations. The selectivity coefficients reported in the literature may differ considerably since they might be determined by different methods such as the separate solution method (SSM), fixed interfering ion method, fixed primary ion method, and specific application method. The selectivity coefficients discussed here are based on results of the SSM method (see **Table 3**). Restrictions may be overcome by using sensor arrays for the determination of the

activity of the primary and the interfering ions combined with a chemometric correction. However, each sensor needs a high quality of performance. The dominating presence of elements with high abundance prevents the use of ISEs for assays of trace element activities in biological specimens or diluted samples.

### Long-Term Stability of Electrode and Lipophilicity of the Electrode Components
